Treatment of the patient with possible glaucoma (ocular hypertension; i.e., patients with IOP >22 mm Hg [>2.9 kPa]) is less controversial with the recent results of the Ocular Hypertensive Treatment Study (OHTS) than it was in the past,.[3] The OHTS helped to identify risk factors for treatment. Patients with IOPs higher than 25 mm Hg (3.3 kPa), vertical cup-to-disk ratio of more than 0.5, and central corneal thickness of less than 555 μm are at greater

risk for developing glaucoma. Risk factors such as family history of glaucoma, black ethnicity, severe myopia, and patients with only one eye must also be taken into consideration when deciding which individuals need treatment.

Patients without risk factors typically are not treated and are monitored for the development of glaucomatous changes. Patients with significant risk factors usually are treated with a well-tolerated topical agent such as a β-blocking agent, an α_2-agonist (brimonidine), a topical carbonic anhydrase inhibitor (CAI), or a prostaglandin analog, depending on individual patient characteristics. Optimally, therapy is initiated in one eye to assess efficacy and tolerance. Use of second- or third-line agents (e.g., pilocarpine or dipivefrin) when first-line agents fail to reduce IOP depends on the risk-to-benefit assessment of each patient. The cost, inconvenience, and frequent adverse effects of combination therapies, anticholinesterase inhibitors, and oral CAIs result in an unfavorable risk-to-benefit ratio for patients with possible glaucoma.[29]

The goal of therapy is to lower the IOP to a level associated with a decreased risk of optic nerve damage, usually at least a 20%, if not a 25% to 30% decrease from the baseline IOP. Greater decreases may be required in high-risk patients or those with higher initial IOPs. Drug therapy should be monitored by measurement of IOP, examination of the optic disk, assessment of the visual fields, and evaluation of the patient for drug adverse effects and compliance with therapy. Patients who are unresponsive to or intolerant of a drug should be switched to an alternative agent rather than given an additional drug. Many clinicians prefer to discontinue all medications for patients who fail to respond adequately to simple topical therapy, closely monitor for development of disk changes or visual field loss, and treat again when such changes occur.[1,2,17–19,29]

More recently, risk calculators have been suggested as a means of determining who are at greatest risk in developing glaucoma. It is hoped that with future improvement in such calculators, one would be able to tailor treatment to those at greatest risk for developing glaucoma.

TREATMENT

Open-Angle Glaucoma

All patients with elevated IOP and characteristic optic disk changes and/or visual field defects not caused by other factors (i.e., glaucoma by definition) should be treated. Recent findings that 1 in 5 patients with "normal" IOP and glaucomatous retinal nerve findings (i.e., normal-tension glaucoma) do not have progression of visual field loss if left untreated have prompted recommendations to monitor normal-tension glaucoma patients without immediate threat of loss of central vision and to treat only when progression is documented. Some controversy exists as to whether the initial therapy of glaucoma should be surgical trabeculectomy (filtering procedure), argon or selective laser trabeculectomy, or medical therapy.[1,2,17,18] Presently, drug therapy remains the most common initial treatment modality. Drug therapy of patients with documented glaucomatous change with either elevated or normal IOP is initiated in a stepwise manner (Fig. 103–5), starting with lower concentrations of a single, well-tolerated topical agent. The goal of therapy is to prevent further visual loss. A "target" IOP is chosen based on a patient baseline IOP and the amount of existing visual field loss. Typically, an initial target IOP reduction of 30% is desired. Greater reductions may be desired for patients with very high baseline IOPs or advanced visual field loss. Patients with normal baseline IOPs (normal-tension glaucoma) may have target IOPs of less than 10 to 12 mm Hg (1.3 to 1.6 kPa).

CLINICAL CONTROVERSY

How much should the IOP be reduced for patients who may have POAG? Although the major clinical trial (OHTS[3]) required a 20% reduction in IOP for patients with ocular hypertension, many clinicians believe a further lowering of IOP may be more beneficial in preventing the progression of ocular hypertension to glaucoma. The American Academy of Ophthalmology Preferred Practice Guidelines suggest 20% to 30% IOP lowering. It remains to be seen if a more aggressive approach earlier in the treatment of the POAG suspect would be more beneficial.

PHARMACOTHERAPEUTIC APPROACH

6 Medications most commonly used to treat glaucoma are the nonselective β-blockers, the prostaglandin analogs (latanoprost, travoprost, and bimatoprost), brimonidine (an α_2-agonist), and the fixed combination products of timolol/dorzolamide or timolol/brimonidine.[21–22]

Before 1996, a β-blocker was used provided no contraindications existed, because this class of drugs has a long history of successful use, providing a combination of clinical efficacy and tolerability. The newer agents, in particular the prostaglandin analogs, brimonidine, and topical CAIs, are also considered suitable first-line therapy or alternative initial therapy for patients with contraindications to or other concerns with β-blockers (see Fig. 103–5). Pilocarpine and dipivefrin are used as third-line therapies because of their increased frequency of adverse effects or reduced efficacy.

Therapy optimally is started as a single agent in one eye (except for patients with very high IOP or advanced visual field loss) to evaluate drug efficacy and tolerance. Monitoring of therapy should be individualized: Initial response to therapy is typically done 4 to 6 weeks after the medication is started. A monocular trial of medication is recommended when possible. Once IOPs reach acceptable levels, the IOP is monitored every 3 to 4 months (more frequently after any change in drug therapy).

CLINICAL CONTROVERSY

The American Academy of Ophthalmology has not designated any agent as the drug of choice for initiation of glaucoma treatment. In recent years, many clinicians have used the prostaglandin analogs because they are dosed once daily and achieve the best pressure reduction. However, others believe that even though the β-blockers are less potent in reducing IOP, they should still be used as initial agents because they are dosed once or twice daily and are available as generic products and thus are more cost-effective.

Visual fields and disk changes are typically monitored annually or earlier if the glaucoma is unstable or there is suspicion of disease worsening. Patients should always be questioned regarding adherence to and tolerance of prescribed therapy. Initial IOP response does not predict long-term IOP control. Using more than one drop per dose does not improve response, but increases the likelihood of adverse effects and the cost of therapy. When using more than one medication, separation of drop instillation of each agent by at least 5 to 10 minutes is suggested to provide optimal ocular contact for each agent.

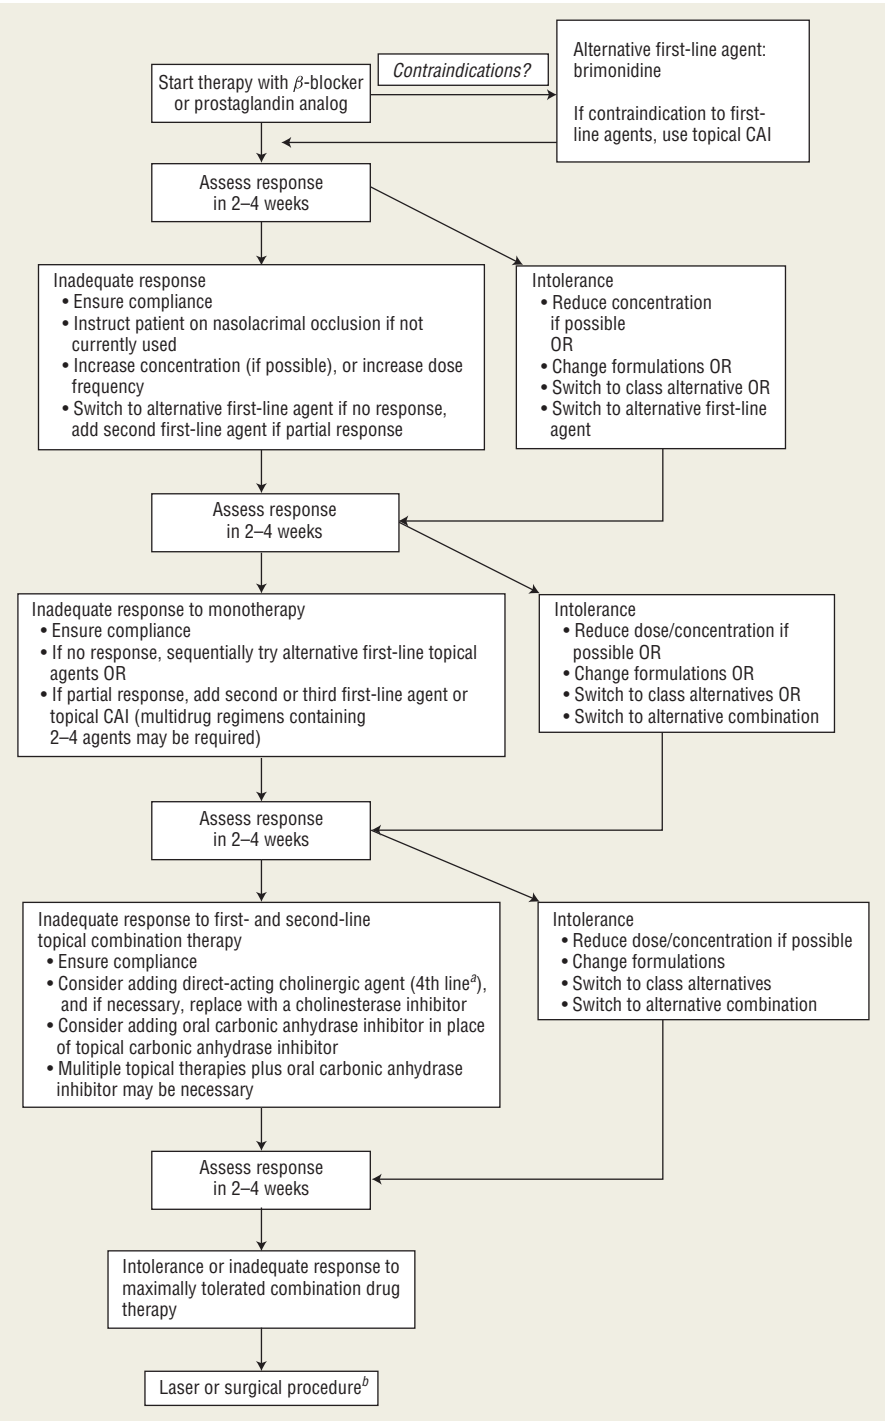

FIGURE 103-5. Algorithm for the pharmacotherapy of open-angle glaucoma. [a]Fourth-line agents not commonly used any longer. [b]Most clinicians believe laser procedure should be performed earlier (e.g., after three-drug maximum, poorly adherent patient). (CAI, carbonic anhydrase inhibitor.)

The value of an agent with which the patient has shown a drop in IOP following an initial response can be measured by discontinuing the medication completely and determining if an increase in IOP occurs. Patients responding to but intolerant of initial therapy may be switched to another drug or to an alternative dosage form of the same medication. For patients failing to respond to the highest tolerated concentrations of an initial drug, a switch to an alternative agent after 1 day of concurrent therapy should be considered. Alternatively, if only a partial response occurs, addition of another topical drug to be used in combination is a possibility. A number of drugs or drug combinations may need to be tried before an effective and well-tolerated regimen is identified. Because of the frequency of adverse effects, carbachol, topical cholinesterase inhibitors, and oral CAIs are considered last-line agents to be used for patients who fail less-toxic combination topical therapy.

NONPHARMACOLOGIC THERAPY: LASER AND SURGICAL PROCEDURES

When drug therapy fails, is not tolerated, or is excessively complicated, surgical procedures such as laser trabeculoplasty (argon or selective) or a surgical trabeculectomy (filtering procedure) may be performed to improve outflow. Laser trabeculoplasty is usually an intermediate step between drug therapy and trabeculectomy. Procedures with higher complication rates, such as those involving placement of draining tubes or destruction of the ciliary body (cyclodestruction), may be required when other methods fail (see Fig. 103–2).[1,2,25]

Surgical methods for reduction of IOP involve the creation of a channel through which aqueous humor can flow from the anterior chamber to the subconjunctival space (filtering bleb), where it is reabsorbed by the vasculature. A major reason for failure of the procedure is healing and scarring of the site.

Modification of the healing process to maintain patency is possible with the use of antiproliferative agents. The antiproliferative agents 5-fluorouracil and mitomycin C are used for patients undergoing glaucoma-filtering surgery to improve success rates by reducing fibroblast proliferation and consequent scarring. Although used most commonly for patients with increased risk for suboptimal surgical outcome (after cataract surgery and a previous failed filtering procedure), use of these agents also improves success in low-risk patients.[30–33]

TREATMENT

Closed-Angle Glaucoma

The goal of initial therapy for acute CAG with high IOP is rapid reduction of the IOP to preserve vision and to avoid surgical or laser iridectomy on a hypertensive, congested eye. Iridectomy (laser or surgical) is the definitive treatment of CAG; it produces a hole in the iris that permits aqueous humor flow to move directly from the posterior chamber to the anterior chamber, opening up the block at the trabecular meshwork. Drug therapy of an acute attack typically involves administration of pilocarpine, hyperosmotic agents, and a secretory inhibitor (a β-blocker, α_2-agonist, prostaglandin $F_2\alpha$ analog, or a topical or systemic CAI). With miosis produced by pilocarpine, the peripheral iris is pulled away from the meshwork. Although traditionally the drug of choice, pilocarpine used as initial therapy is controversial. Miotics may worsen angle closure by increasing pupillary block and producing anterior movement of the lens because of drug-induced accommodation.

At IOPs greater than 60 mm Hg (8.0 kPa), the iris may be ischemic and unresponsive to miotics; as the pressure drops and the iris responds, miosis occurs. During this time, the urge to use excessive amounts of pilocarpine must be resisted. The dose of pilocarpine commonly used is a 1% or 2% solution instilled every 5 minutes for two or three doses and then every 4 to 6 hours. However, many practitioners withhold application of pilocarpine until the IOP has been reduced by other agents, and then apply a single drop of 1% to 2% pilocarpine to produce miosis. In either case, the unaffected contralateral eye should be treated with the miotic every 6 hours to prevent development of angle closure. An osmotic agent also is commonly administered because these drugs produce the most rapid decrease in IOP. Oral glycerin 1 to 2 g/kg can be used if an oral agent is tolerated; if not, intravenous mannitol 1 to 2 g/kg should be used. Osmotic agents reduce IOP by withdrawing water from the eye secondary to the osmotic gradient between the blood and the eyes. These drugs are among the first-line agents in the short-term treatment of CAG or other forms of acute very high IOP elevations. Topical corticosteroids often are used to reduce the ocular inflammation and reduce the development of synechiae in CAG eyes. In classic CAG, once the IOP is controlled, pilocarpine may be given every 6 hours until iridectomy is performed. Patients failing therapy altogether will require an emergency iridectomy.

Peripheral iridectomy essentially "cures" primary CAG without significant synechiae. Long-term drug therapy is not used unless IOP remains high because of the presence of synechiae blocking the trabecular meshwork or concurrent POAG. In such cases, the pharmacotherapeutic approach is essentially identical to that for the POAG patient, or laser or surgical procedures are performed.[1,2]

PHARMACOLOGIC AGENTS USED IN GLAUCOMA

β-BLOCKING DRUGS

The topical β-blocking agents are one of the most commonly used antiglaucoma medications (Table 103–4). β-Blockers lower IOP by 20% to 30% with a minimum of local ocular adverse effects. These are commonly one of the agents of first choice in treating POAG if no contraindications exist.[1,2,17–19,34–36]

The β-blocking agents produce ocular hypotensive effects by decreasing the production of aqueous humor by the ciliary body without producing substantial effects on aqueous humor outflow facility. The mechanism by which β-blockers decrease aqueous humor inflow remains controversial, but it is most frequently attributed to β_2-adrenergic receptor blockade in the ciliary body.

Five ophthalmic β-blockers are presently available: timolol, levobunolol, metipranolol, carteolol, and betaxolol. Timolol, levobunolol, and metipranolol are nonspecific β-blocking agents, whereas betaxolol is a relatively β_1-selective agent. Carteolol is a nonspecific blocker with intrinsic sympathomimetic activity. Despite differences in potency, selectivity, lipophilicity, and intrinsic sympathomimetic activity, the five agents reduce IOP to a similar degree, although betaxolol has been reported to produce somewhat less lowering of IOP than timolol and levobunolol. Levobunolol may be more effective than timolol and betaxolol in reducing postcataract surgery IOP increases. Levobunolol solution is more effective in controlling IOP than other agents when given as aqueous solutions on a once-daily schedule (up to 70% of patients). Timolol in the form of a gel-forming solution (Timoptic-XE) provides equivalent IOP control with once-daily administration when compared with the same concentration of the aqueous solution administered twice daily. The choice of a specific β-blocking agent generally is based on differences in adverse effect potential, individual patient response, and cost. Long-term treatment with topical β-blockers results in tachyphylaxis in 20% to 25% of patients. The mean IOP reduction from baseline may be smaller for patients receiving topical β-blockers with concurrent systemic β-blockers.[29]

Local adverse effects with β-blockers usually are tolerable, although stinging on application occurs commonly, particularly with betaxolol solution (less with betaxolol suspension) and metipranolol. Other local effects include dry eyes, corneal anesthesia, blepharitis, blurred vision, and, rarely, conjunctivitis, uveitis, and keratitis. Some local reactions may be a result of preservatives used in the commercially available products. Switching from one agent to another or switching the type of formulation may improve tolerance in patients experiencing local adverse effects.

Systemic effects are the most important adverse effects of β-blockers. Drug absorbed systematically may produce decreased heart rate, reduced blood pressure, negative inotropic effects, conduction defects, bronchospasm, central nervous system effects, and alteration of serum lipids and may block the symptoms of hypoglycemia. The β_1-specific agents betaxolol and possibly carteolol (as a consequence of intrinsic sympathomimetic activity) are less likely to produce the systemic adverse effects caused by β-adrenergic blockade, such as the cardiac effects and bronchospasm, but a real risk still exists. The use of timolol as a gel-forming liquid or betaxolol as a suspension allows for administration of less drug per day and, therefore, reduces the chance for systemic adverse effects compared with the aqueous solutions.

TABLE 103-4 Topical Drugs Used in the Treatment of Open-Angle Glaucoma

Drug	Pharmacologic Properties	Common Brand Names	Dose Form	Strength (%)	Usual Dose[a]	Mechanism of Action
β-Adrenergic blocking agents						
Betaxolol	Relative β_1-selective	Generic	Solution	0.5	1 drop twice a day	All reduce aqueous production of ciliary body
		Betoptic-S	Suspension	0.25	1 drop twice a day	
Carteolol	Nonselective, intrinsic sympathomimetic activity	Generic	Solution	1	1 drop twice a day	
Levobunolol	Nonselective	Betagan	Solution	0.25, 0.5	1 drop twice a day	
Metipranolol	Nonselective	OptiPranolol	Solution	0.3	1 drop twice a day	
Timolol	Nonselective	Timoptic, Betimol, Istalol	Solution	0.25, 0.5	1 drop every day–one to two times a day	
		Timoptic-XE	Gelling solution	0.25, 0.5	1 drop every day[a]	
Nonspecific adrenergic agonists						
Dipivefrin	Prodrug	Propine	Solution	0.1	1 drop twice a day	Increased aqueous humor outflow
α_2-Adrenergic agonists						
Apraclonidine	Specific α_2-agonists	Iopidine	Solution	0.5, 1	1 drop two to three times a day	Both reduce aqueous humor production; brimonidine known to also increase uveoscleral outflow; only brimonidine has primary indication
Brimonidine		Alphagan P	Solution	0.15, 0.1	1 drop two to three times a day	
Cholinergic agonists direct acting						
Carbachol	Irreversible	Carboptic, Isopto Carbachol	Solution	1.5, 3	1 drop two to three times a day	All increase aqueous humor outflow through trabecular meshwork
Pilocarpine	Irreversible	Isopto Carpine, Pilocar	Solution	0.25, 0.5, 1, 2, 4, 6, 8, 10	1 drop two to three times a day 1 drop four times a day	
		Pilopine HS	Gel	4	Every 24 h at bedtime	
Cholinesterase inhibitors						
Echothiophate		Phospholine Iodide	Solution	0.125	Once or twice a day	
Carbonic anhydrase inhibitors						
Topical						
Brinzolamide	Carbonic anhydrase type II inhibition	Azopt	Suspension	1	Two to three times a day	All reduce aqueous humor production of ciliary body
Dorzolamide		Trusopt	Solution	2	Two to three times a day	
Systemic						
Acetazolamide		Generic	Tablet	125 mg, 250 mg	125–250 mg two to four times a day	
		Injection	500 mg/vial	250–500 mg		
		Diamox Sequels	Capsule	500 mg	500 mg twice a day	
Methazolamide		Generic	Tablet	25 mg, 50 mg	25–50 mg two to three times a day	
Prostaglandin analogs						
Latanoprost	Prostaglandin $F_{2\alpha}$ analog	Xalatan	Solution	0.005	1 drop every night	Increases aqueous uveoscleral outflow and to a lesser extent trabecular outflow
Bimatoprost	Prostamide analog	Lumigan	Solution	0.03	1 drop every night	
Travoprost		Travatan Z	Solution	0.004	1 drop every night	
Combinations						
Timolol-dorzolamide		Cosopt	Solution	Timolol 0.5% dorzolamide 2%	1 drop twice daily	
Timolol-brimonidine		Combigan	Solution	Timolol 0.5% brimonide 0.2%	1 drop twice daily	

[a]Use of nasolacrimal occlusion will increase the number of patients successfully treated with longer dosage intervals.

Because of their systemic adverse effects, all ophthalmic β-blockers should be used with caution for patients with pulmonary diseases, sinus bradycardia, second- or third-degree heart block, congestive heart failure, atherosclerosis, diabetes, and myasthenia gravis, as well as for patients receiving oral β-blocker therapy. Use of nasolacrimal occlusion (NLO; see Patient Education below for description) technique during administration reduces the risk or severity of systemic adverse effects, as well as optimizes response. Overall, β-adrenergic blocking agents are well tolerated by most patients, and most potential problems can be avoided by appropriate patient evaluation, drug choice, and monitoring of drug therapy. For patients failing or having an inadequate response to single-drug therapy with

a β-blocking agent, the addition of a CAI, parasympathomimetic agent, prostaglandin analog, or an α_2-adrenergic receptor agonist usually will result in additional IOP reduction. Dipivefrin added to a β-blocking agent (particularly nonspecific β-blockers) usually results in only minimal additional IOP reduction.[1–3,17–19,29]

α_2-ADRENERGIC AGONISTS

Brimonidine and the less lipid-soluble and less receptor-selective apraclonidine are α_2-adrenergic agonists structurally similar to clonidine. Apraclonidine is indicated and brimonidine is effective for prevention or control of postoperative or postlaser treatment increases in IOP. Brimonidine is considered a first-line or adjunctive agent in the therapy of POAG, and apraclonidine is seen as a second-line or adjunctive therapy. Use of apraclonidine has fallen dramatically because of a high incidence of loss of control of IOP (tachyphylaxis) and a more severe and prevalent ocular allergy rate.

α_2-Agonists reduce IOP by decreasing the rate of aqueous humor production (some increase in uveoscleral outflow also occurs with brimonidine). The drugs reduce IOP by 18% to 27% at peak (2 to 5 hours) and by 10% at 8 to 12 hours. Comparative trials demonstrate a reduction in IOP similar to that obtained with 0.5% timolol. Use of brimonidine 0.2% every 8 to 12 hours appears to provide maximum IOP-lowering effects in long-term use. Use of NLO (see Patient Education below) may improve response and allow the longer dosing frequency (i.e., every 12 hours). Combinations of α_2-agonists with β-blockers, prostaglandin analogs, or CAIs produce additional IOP reduction.

An allergic-type reaction characterized by lid edema, eye discomfort, foreign-object sensation, itching, and hyperemia occurs in approximately 30% of patients with apraclonidine. Brimonidine produces this adverse effect in up to 8% of patients. This reaction commonly necessitates drug discontinuation. Systemic adverse effects with brimonidine include dizziness, fatigue, somnolence, dry mouth, and possibly a slight reduction in blood pressure and pulse. α_2-Agonists should be used with caution for patients with cardiovascular diseases, renal compromise, cerebrovascular disease, and diabetes, as well as in those taking antihypertensives and other cardiovascular drugs, monoamine oxidase inhibitors, and tricyclic antidepressants.

Brimonidine is also contraindicated in infants because of apneic spells and hypotensive reactions. In terms of overall efficacy and tolerability, brimonidine approximates that achieved with β-blockers.[1,2,17–19,29]

Brimonidine purite 0.15% or 0.1% is a formulation of brimonidine in a lower concentration than the original product that contains a less-toxic preservative than the most commonly employed benzalkonium chloride. The newer formulations are as effective as the original because the more neutral pH of brimonidine purite (0.15% pH 7.2; 0.1% pH 7.7) allows for higher concentrations of brimonidine in the aqueous humor with a similar reduction in IOP and a reduced incidence of ocular allergy.[29]

The combination product timolol 0.5% and brimonidine 0.2% (Combigan) may provide additional IOP lowering than either agent alone. A new treatment option, this product is marketed in solution that is dosed twice daily.

CLINICAL CONTROVERSY

Many animal trials demonstrate that brimonidine has excellent neuroprotective properties.[12–15] Some clinicians believe that one of the major advantages of using brimonidine lies in its potential neuroprotective properties. However, neuroprotection has not been demonstrated in human trials.

PROSTAGLANDIN ANALOGS

The prostaglandin analogs, including latanoprost, travoprost, and bimatoprost, reduce IOP by increasing the uveoscleral and, to a lesser extent, trabecular outflow of aqueous humor. Some differences in receptor sites and mechanisms of action may exist between the two prostaglandins (latanoprost and travoprost), the prostamide (bimatoprost). Bimatoprost may be slightly more effective in lowering IOP, getting a larger percentage of patients to lower IOPs, and for patients unresponsive to latanoprost.[29,37–39] If the patient does not respond to trovaprost or latanoprost, a switch to bimatoprost may be beneficial.[39]

Reduction in IOP with once-daily doses of prostaglandin $F_2\alpha$ analogs (a 25% to 35% reduction) is often greater than that seen with timolol 0.5% twice daily. In addition, nocturnal control of IOP is improved compared with timolol. Interestingly, administration of prostaglandin $F_2\alpha$ analogs twice daily may reduce the IOP similarly to once-daily dosing. The drugs are administered at nighttime, although they are probably as effective if given in the morning.

Prostaglandin analogs are well tolerated and produce fewer systemic adverse effects than timolol. Local ocular tolerance generally is good, but ocular reactions such as punctate corneal erosions and conjunctival hyperemia do occur. Local intolerance occurs in 10% to 25% of patients with these agents.

With prostaglandin analogs, altered iris pigmentation occurs in 15% to 30% of patients, particularly those with mixed-color irises (blue-brown, green-brown, blue-gray-brown, or yellow-brown eyes), which become browner in color over 3 to 12 months. The change in iris pigmentation will often appear within 2 years, and long-term consequences of this pigment change appear to be mostly cosmetic but irreversible upon discontinuation. Hypertrichosis is common and reverses upon discontinuation of the drug. Hyperpigmentation around the lids and lashes has also been reported and appears to reverse upon discontinuation.

These agents are associated with uveitis, and caution is recommended for patients with ocular inflammatory conditions. Cystoid macular edema also has been reported. Cases of worsening of herpetic keratitis have been reported.

Prostaglandin analogs can be used in combination with other antiglaucoma agents for additional IOP control because of their unique mechanism of action. Given their excellent efficacy and side-effect profile, prostaglandin analogs provide effective monotherapy or adjunctive therapy for patients who are not responding to or tolerating other agents. The use of prostaglandin analogs as first-line therapy in POAG is approved for latanoprost and bimatoprost. Long-term studies demonstrate these agents are safe, efficacious, and well tolerated in glaucoma therapy.[17–19,29,37,38]

CARBONIC ANHYDRASE INHIBITORS

Topical Agents

CAIs reduce IOP by decreasing ciliary body aqueous humor secretion. CAIs appear to inhibit aqueous production by blocking active secretion of sodium and bicarbonate ions from the ciliary body to the aqueous humor.[1,2,29] Topical CAIs such as dorzolamide and brinzolamide are well tolerated and are indicated for monotherapy or adjunctive therapy of OAG and ocular hypertension. Relatively specific inhibitors of carbonic anhydrase enzyme II such as dorzolamide and brinzolamide reduce IOP by 15% to 26%.

Topical CAIs generally are well tolerated. Local adverse effects include transient burning and stinging, ocular discomfort and transient blurred vision, tearing, and, rarely, conjunctivitis, lid reactions, and photophobia. A superficial punctate keratitis occurs in 10% to 15% of patients. Brinzolamide produces more blurry vision but is less stinging than dorzolamide. Systemic adverse effects are

unusual despite the accumulation of drug in red blood cells. Because of their favorable adverse-effect profile, topical CAIs provide a useful alternative agent for monotherapy or adjunctive therapy for patients with inadequate response to or who are unable to use other agents. The drugs may add additional IOP reduction for patients using other single or multiple topical agents. The usual dose of a topical CAI is 1 drop every 8 to 12 hours. Administration every 12 hours produces somewhat less IOP reduction than administration every 8 hours. Use of NLO should optimize response to CAI given at any interval.[1,2,17–19,29,34,36] The combination product timolol 0.5% and dorzolamide 2% (Cosopt) is dosed twice daily and produces equivalent IOP lowering to each product dosed separately.

Systemic Agents

Systemic CAIs are indicated for patients failing to respond to or tolerate maximum topical therapy. Systemic and topical CAIs should not be used in combination because no data exist concerning improved IOP reduction, and the risk for systemic adverse effects is increased. Oral CAIs reduce aqueous humor inflow by 40% to 60% and IOP by 25% to 40%. The available systemic CAIs (see Table 103–4) produce equivalent IOP reduction but differ for potency, adverse effects, dosage forms, and duration of action. Despite their excellent effects on elevated IOP of any etiology, the systemic CAIs frequently produce intolerable adverse effects. As a result, CAIs are considered third-line agents in the treatment of POAG and often used for short-term administration to lower IOP.

On average, only 30% to 60% of patients are able to tolerate oral CAI therapy for prolonged periods. Intolerance to CAI therapy results most commonly from a symptom complex attributable to systemic acidosis and including malaise, fatigue, anorexia, nausea, weight loss, altered taste, depression, and decreased libido. Other adverse effects include renal calculi, increased uric acid, blood dyscrasias, diuresis, and myopia. Elderly patients do not tolerate CAIs as well as younger patients. The available CAIs produce the same spectrum of adverse effects; however, the drugs differ in the frequency and severity of the adverse effects listed.

CAIs should be used with caution for patients with sulfa allergies (all CAIs, topical or systemic, contain sulfonamide moieties), sickle cell disease, respiratory acidosis, pulmonary disorders, renal calculi, electrolyte imbalance, hepatic disease, renal disease, diabetes mellitus, or Addison disease. Concurrent use of a CAI and a diuretic may rapidly produce hypokalemia. High-dose salicylate therapy may increase the acidosis produced by CAIs, whereas the acidosis produced by CAIs may increase the toxicity of salicylates.[1,2,17–19,21,29,34,35]

PARASYMPATHOMIMETIC AGENTS

The parasympathomimetic (cholinergic) agents reduce IOP by increasing aqueous humor trabecular outflow. The increase in outflow is a result of physically pulling open the trabecular meshwork secondary to ciliary muscle contraction, thereby reducing resistance to outflow. These agents may reduce uveoscleral outflow. Cholinergic agents work well to decrease IOP, but their use as primary or even adjunctive agents in the treatment of glaucoma has decreased significantly because of local ocular adverse effects and/or frequent dosing requirements.

Pilocarpine, the parasympathomimetic agent of choice in POAG, is available as an ophthalmic solution, an ocular insert, and a hydrophilic polymer gel (see Table 103–4). Pilocarpine produces similar (20% to 30%) reductions in IOP as those seen with β-blocking agents. Pilocarpine in POAG or "glaucoma suspects" is initiated as 0.5% or 1% solution, 1 drop three to four times daily. The use of NLO improves response and reduces the need for an every-6-hour dosing frequency. The use of 1 drop of 2% pilocarpine every 6 to 12 hours and NLO provides optimal response in many patients. Both drug concentration and frequency may be increased if IOP reduction is inadequate. Patients with darkly pigmented eyes frequently require higher concentrations of pilocarpine than do patients with lightly pigmented eyes. Concentrations of pilocarpine above 4% rarely improve IOP control in patients, other than those patients with darkly pigmented eyes.

Pilocarpine 4% gel (Pilopine HS) once daily is equivalent to treatment with pilocarpine solution 4% four times daily or timolol 0.5% twice daily. When using every-24-hour dosing of pilocarpine gel, the adequacy of IOP control late in the dosing interval should be confirmed. Ocular adverse effects of pilocarpine include miosis, which decreases night vision and vision in patients with central cataracts. Visual field constriction may be seen secondary to miosis and should be considered when evaluating visual field changes in a glaucoma patient. Pilocarpine ciliary muscle contraction produces accommodative spasm, particularly in young patients still able to accommodate (prepresbyopic). Pilocarpine may also produce frontal headache, brow ache, periorbital pain, eyelid twitching, and conjunctival irritation or injection early in therapy, which tends to decrease in severity over 3 to 5 weeks of continued therapy.

Cholinergics produce a breakdown of the blood–aqueous humor barrier and may result in a worsening of an ocular inflammatory reaction or condition. Systemic cholinergic adverse effects of pilocarpine—such as diaphoresis, nausea, vomiting, diarrhea, cramping, urinary frequency, bronchospasm, and heart block—are rare but may be seen in patients who are using products with high pilocarpine concentrations (6% to 8%) or in those patients who are using such products overzealously in treatment of acute-angle closure. Other adverse effects associated with direct-acting miotics include retinal tears or detachment, allergic reaction, permanent miosis, cataracts, precipitation of CAG, and, rarely, miotic cysts of the pupillary margin.

Carbachol is a potent direct-acting miotic agent; its duration of action is longer than that of pilocarpine (8 to 10 hours) because of resistance to hydrolysis by cholinesterases. This drug also may act as a weak inhibitor of cholinesterase. Patients with an inadequate response to or intolerance of pilocarpine as a result of ocular irritation or allergy frequently do well on carbachol. The ocular and systemic adverse effects of carbachol are similar to but more frequent, constant, and severe than those of pilocarpine.[1,2,17–19,29,34,35] Clinical use of carbachol is limited and may not be commercially available in the near future.

The cholinesterase inhibitors used most commonly in the treatment of POAG are the long-acting, relatively irreversible agents demecarium and echothiophate (limited commercial availability; see Table 103–4). These agents are potent inhibitors of pseudocholinesterase, but they also inhibit true cholinesterase. Because of the serious ocular and systemic toxic effects of these agents, the cholinesterase inhibitors are reserved primarily for patients who are either not responding to or are intolerant of other therapy. Because of their cataractogenic properties, most ophthalmologists use these agents only for patients without lenses (aphakia) and for patients with artificial lenses (pseudophakia). The ocular and periocular parasympathomimetic adverse effects are more common and more severe than with pilocarpine or carbachol.

In addition to the parasympathomimetic effects, the cholinesterase inhibitors may produce severe fibrinous iritis (particularly with the irreversible inhibitors), synechiae, iris cysts, conjunctival thickening, occlusion of the nasolacrimal ducts, and cataracts. The inhibition of systemic pseudocholinesterase by these agents decreases the rate of succinylcholine hydrolysis, resulting in prolonged muscle paralysis. Cholinesterase inhibitors should be discontinued at least 2 weeks before procedures in which succinylcholine is used.

The role of cholinesterase inhibitors in glaucoma is limited by the frequency and potential toxicity of these agents. For phakic patients, cholinesterase inhibitors should be administered only if intolerance or failure results with other antiglaucoma medications. Cholinesterase inhibitors have been shown to provide additional IOP-lowering effects when used with β-blockers, CAIs, and sympathomimetic (adrenergic) agents. As with all agents for glaucoma, therapy should be initiated with lower concentrations of these agents. A once-daily administration frequency should be used for most patients unless very high IOP is present.

Use of NLO likely improves response, reduces systemic adverse effects, and should be performed by all patients administering cholinesterase inhibitors. These agents should be used with caution for patients with asthma, retinal detachments, narrow angles, bradycardia, hypotension, heart failure, Down syndrome, epilepsy, parkinsonism, peptic ulcer, and ocular inflammation, as well as in those receiving cholinesterase inhibitor therapy for myasthenia gravis or exposure to carbamate or organophosphate insecticides and pesticides.[1,2,17–19,29,34,35]

EPINEPHRINE AND DIPIVEFRIN

The mechanism of action by which epinephrine lowers IOP has not been fully elucidated; however, a β_2-receptor–mediated increase in outflow facility through the trabecular meshwork and the uveoscleral route appears to be the primary mechanism. Compared with β-blockers or miotics, epinephrine is less effective for reducing IOP. With the advent of the better-tolerated and more-efficacious agents to treat glaucoma, the clinical use of epinephrines has decreased dramatically.

Epinephrine is not commercially available in the United States anymore. Use of the prodrug of epinephrine, dipivefrin, allows use of lower concentrations secondary to improved intraocular absorption (10- to 15-fold higher). The 0.1% dipivefrin produces equivalent IOP reduction to 1% to 2% epinephrine. Consequently, dipivefrin may be tolerated by patients who are unable to tolerate epinephrine solutions.

A factor limiting the usefulness of dipivefrin is the high frequency of local ocular adverse effects. Tearing, burning, ocular discomfort, brow ache, conjunctival hyperemia, punctate keratopathy, allergic blepharoconjunctivitis, rare loss of eyelashes, stenosis of the nasolacrimal duct, and blurred vision may occur. Prolonged use (>1 year) may result in deposition of pigment (adrenochrome) in the conjunctiva and cornea. Pigment also may deposit in soft contact lenses, turning them black. These adverse effects occur less frequently with dipivefrin than with epinephrine. Dipivefrin may produce mydriasis (particularly when combined with a β-blocker) and may precipitate acute CAG in patients with narrow anterior chambers. A transient increase in IOP may occur with initial therapy, particularly for patients not using other antiglaucoma medications. A relative contraindication to the use of dipivefrin is aphakia (i.e., after cataract removal) or lens dislocation because of the development of swelling of the macular portion of the retina. The edema is dose dependent and disappears with drug discontinuation.

Systemic adverse effects of epinephrine and dipivefrin include headache, faintness, increased blood pressure, tachycardia, arrhythmias, tremor, pallor, anxiety, and increased perspiration. Epinephrine and dipivefrin should be used with caution for patients with cardiovascular diseases, cerebrovascular diseases, aphakia, CAG, hyperthyroidism, and diabetes mellitus, as well as for patients undergoing anesthesia with halogenated hydrocarbon anesthetics. Using NLO with epinephrine and dipivefrin will improve therapeutic response and reduce the risk of systemic adverse effects.[1,2,17–19,29,34,35]

FUTURE DRUG THERAPIES

It is hoped that new agents, improved formulations, and novel approaches to the reduction of IOP and other methods of prevention of glaucomatous visual field loss will provide more effective and better-tolerated therapies. Agents that are neuroprotective and act through mechanisms other than IOP reduction are likely to be part of glaucoma therapy in the future.[13–15,40]

EVALUATION OF THERAPEUTIC OUTCOMES

The ultimate goal of drug therapy for the patient with glaucoma is to preserve visual function through reduction of IOP to a level at which no further optic nerve damage occurs. Because of the poor relationship between IOP and optic nerve damage, no specific target IOP exists. Indeed, drugs used to treat glaucoma may act in part to halt visual field loss through mechanisms separate from or in addition to IOP reduction, such as improvements in retinal or choroidal blood flow. Often a 25% to 30% reduction is desired, but greater reductions (40% to 50%) may be desired for patients with initially high IOPs. For patients with glaucoma, an IOP of less than 21 mm Hg (2.8 kPa) generally is desired, with progressively lower target pressures needed for greater levels of glaucomatous damage. Even lower IOPs (possibly even below 10 mm Hg [1.3 kPa]) are required for patients with very advanced disease, those showing continued damage at higher IOPs, and those with normal-tension glaucoma and pretreatment pressures in the low to middle teens. The IOP considered acceptable for a patient is often a balance of desired IOP and acceptable treatment-related toxicity and of patient quality of life.

PATIENT EDUCATION

7 An important consideration for patients failing to respond to drug therapy is adherence. Poor adherence or nonadherence occurs in 25% to 60% of glaucoma patients.

A large percentage of patients also fail to use topical ophthalmic drugs correctly. Patients should be taught the following procedure:

1. Wash and dry the hands; shake the bottle if it contains a suspension.
2. With a forefinger, pull down the outer portion of the lower eyelid to form a "pocket" to receive the drop.
3. Grasp the dropper bottle between the thumb and fingers with the hand braced against the cheek or nose and the head held upward.
4. Place the dropper over the eye while looking at the tip of the bottle; then look up and place a single drop in the eye.
5. The lids should be closed (but not squeezed or rubbed) for 1 to 3 minutes after instillation. This increases the ocular availability of the drug.
6. Recap bottle and store as instructed.

Note that many patients are physically unable to administer their own eyedrops without assistance. NLO also should be used to improve ocular bioavailability and reduce systemic absorption.[1,2,17–19,29,34,35] The patient induces NLO for 1 to 3 minutes by closing the eyes and placing the index finger over the nasolacrimal drainage system in the inner corner of the eye. This maneuver, as well as eyelid closure itself, decreases nasolacrimal drainage of drug, thereby decreasing the amount of drug available for systemic absorption by the nasopharyngeal mucosa. The use of NLO may

improve drug response significantly, reduce adverse effects, and allow less-frequent dosing intervals and the use of lower drug concentrations.

Use of more than 1 drop per dose increases costs, does not improve response significantly, and may increase adverse effects. When two drugs are to be administered, instillations should be separated by at least 3 to 5 minutes (preferably 10 minutes) to prevent the drug administered first from being washed out. The patient should be taught not to touch the dropper bottle tip with eye, hands, or any surface.

Adherence to glaucoma therapy usually is inadequate, and it always should be considered as a possible cause of drug therapy failure. Assessment of adherence by healthcare providers generally is poor; so all patients should be encouraged continually to administer prescribed therapy diligently as instructed. To improve adherence, the patient, family, and care providers should be fully informed of the expectations of therapy and the need to continue therapy despite a lack of symptoms. Possible adverse effects of the medication and ways to reduce them should be discussed. Adherence will be improved by good communication, simplified and well tolerated dosing regimens, reminder devices, education, close monitoring, and individualized care planning.[1,2,17–19,29,41]

CONCLUSIONS

The glaucomas are a group of primary and secondary diseases whose management presents a considerable challenge to the clinician. Successful therapy requires rational use of antiglaucoma medications and patient adherence to the selected regimen, combined with conscientious monitoring for adverse effects and disease progression. The reward for successful therapy is considerable—the maintenance of vision. The overview of the clinical findings, pathology, and drug therapy presented in this chapter provides the clinician with the fundamentals necessary to understand and treat glaucoma.

ABBREVIATIONS

CAG: closed-angle glaucoma

CAI: carbonic anhydrase inhibitor

IOP: intraocular pressure

NLO: nasolacrimal occlusion

OHTS: Ocular Hypertensive Treatment Study

POAG: primary open-angle glaucoma

CHAPTER 104

Allergic Rhinitis

J. RUSSELL MAY AND PHILIP H. SMITH

KEY CONCEPTS

1. Allergic rhinitis is a common disease. Treatment is justified in most cases because of the potential for complications.
2. Because an immediate immune response to allergens results in release of inflammatory mediators that cause allergic rhinitis symptoms, patients must understand the rationale for the proper timing and administration of prophylactic regimens.
3. Proven therapies include avoidance of allergens and pharmacologic management with antihistamines, topical and systemic decongestants, topical steroids, cromolyn sodium, leukotriene receptor antagonists, and immunotherapy.
4. Immunotherapy can be highly successful, offering long-term benefits, but expense, potential risks, and a major time commitment makes proper patient selection critical.

Allergic rhinitis involves inflammation of the nasal mucous membrane. In a sensitized individual, allergic rhinitis occurs when inhaled allergenic materials contact mucous membranes and elicit a specific response mediated by immunoglobulin E (IgE). This acute response involves the release of inflammatory mediators and is characterized by sneezing, nasal itching, and watery rhinorrhea, often associated with nasal congestion. Itching of the throat, eyes, and ears frequently accompanies allergic rhinitis.

Allergic rhinitis may be regarded as seasonal allergic rhinitis, commonly known as *hay fever*, or perennial allergic rhinitis (increasingly called *intermittent* and *persistent*). Seasonal rhinitis occurs in response to specific allergens usually present at predictable times of the year, during plants' blooming seasons (typically the spring or fall). Seasonal allergens include pollen from trees, grasses, and weeds. Perennial allergic rhinitis is a year-round disease caused by nonseasonal allergens, such as house-dust mites, animal dander, and molds, or multiple allergic sensitivities. It typically results in subtler, chronic symptoms. Many patients have a combination of these two types of allergic rhinitis, with symptoms year-round and seasonal exacerbations. About one third to one half of sufferers have recognizable seasonal disease with the remainder having perennial or a combination of both.[1]

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY AND ETIOLOGY

1 Allergic rhinitis is one of the most common medical disorders found in humans. Using questionnaires, investigators have found the prevalence of seasonal and perennial allergic rhinitis, respectively, to range between 1% and 40% and from 1% to 13% with some believing the percentage to be higher.[2,3] It ranks as the sixth most prevalent chronic illness in the United States.[1] In the populations of Europe, United States, Australia, and New Zealand, the prevalence of an IgE sensitization to aeroallergens measured by allergen-specific IgE in serum or skin tests is more than 40% to 50%.[3] Most but not all of these patients have allergic rhinitis and/or asthma. Patients are limited in their ability to carry out normal daily functions; higher levels of general fatigue, mental fatigue, anxiety, depressive disorders, and learning disabilities (secondary to sleep loss and fatigue) are seen.[3,4]

In addition, the impact of allergic rhinitis goes well beyond these central-nervous-system issues. Allergic rhinitis is associated with several other serious medical conditions, including asthma, chronic rhinosinusitis, otitis media, nasal polyposis, respiratory infections, and orthodontic malocclusions.

PREDISPOSING FACTORS

The development of allergic rhinitis is determined by genetics, allergen exposure, and the presence of other risk factors. A family history of allergic rhinitis, atopic dermatitis, or asthma suggests that rhinitis is allergic. The risk of developing allergic disease appears to increase if one parent is atopic and further increases if two are allergic; however, small sample sizes and the lack of reproducibility prevent generalization.[3]

Allergen exposure is another necessary factor. For allergic rhinitis to occur, an individual must be exposed over time to a protein that elicits the allergic response in that individual. Many potential sufferers never develop symptoms because they do not come into contact with the allergen that would produce symptoms in them.

Evidence suggests microbial exposure in the first years of life could help prevent allergic disease by stimulating a nonatopic immune response.[5] Farm children are exposed to higher concentrations of endotoxin, derived from cell walls of gram-negative bacteria, in stables and in dust around the farmhouse. Consumption of nonpasteurized farm milk may cause further exposure. This concept has led to the idea that allergic disease could be prevented by proactively increasing exposure to harmless bacteria early in life (see Alternative Treatment Options below). This could explain why positive skin tests indicating allergen sensitization have been observed more frequently for people in higher socioeconomic classes and for people who live in suburban areas.

Other predisposing factors include an elevated serum IgE (>100 international units/mL [>100 kIU/L]) before the age of 6 years, eczema, and heavy exposure to secondhand cigarette smoke.[6]

ALLERGENS

Allergens that produce seasonal rhinitis include protein components of airborne pollen grains, often enzymes, from a variety of trees, grasses, and weeds. Ragweed and grass pollen are the most common offenders in the United States; however, this varies with the geographic region. In general, tree pollens cause symptoms in the spring, grass pollens cause symptoms in the late spring and summer, and weed pollens are the culprits from late summer through fall. Patients who are hypersensitive to all three may have overlapping problem periods and may be described as having perennial rhinitis when they are actually experiencing prolonged seasonal rhinitis. For this reason and the fact that most patients with seasonal problems are sensitive to at least some of the perennial allergens, there is little practical difference between the two types of allergic rhinitis. To complicate matters further, the antigenic components of many grasses—including fescue, Kentucky bluegrass, orchard, redtop, and timothy—cross-react extensively. By contrast, tree allergens are antigenically distinct. These trees include ash, beech, birch, cedar, hickory, maple, oak, poplar, and sycamore. Flowering plants that depend on insect pollination do not cause allergic rhinitis because their pollen is too heavy and sticky and is not carried in the air.

Mold spores are also important but cause allergy much less frequently. Various spores are present year-round; however, mold growth on decaying vegetation increases seasonally. Just walking through uncut fields or raking leaves can increase exposure. Thus, mold spores can be responsible for both perennial and seasonal allergies.

Indoor allergens are always present. Most important among these are house-dust mite fecal proteins, animal dander, cockroaches, and certain mold species. Dust mite levels are on the rise, possibly because of the construction of energy-efficient homes and offices with reduced ventilation and increased humidity, use of wall-to-wall carpeting, and the popularity of cool-water detergents and cold-water washing.[3]

PATHOPHYSIOLOGY

Knowledge of nasal physiology aids in the understanding of allergic rhinitis. The nose performs three "air conditioning" functions to prepare incoming gases for the lungs. During the fraction of a second that air is in the nose, it is heated, humidified, and cleaned. The cleaning process plays a role in the development of allergic rhinitis. As the air passes through the nose, the turbulence throws particulate matter against a mucous blanket. The rhythmic movements of the nasal cilia cause the mucous blanket to move posteriorly at approximately 9 mm/min, where it is eventually swallowed; thus, trapped foreign particles are removed via the gastrointestinal tract and do not reach the lungs. It also concentrates foreign protein material into the posterior throat, where lymph tissues identify them and produce most of the allergic antibody that drives allergic rhinitis.

The vascular tissue in the nose is erectile. Stimulation of sympathetic fibers causes vasoconstriction, reduction in erectile tissue size and the size of the membranes and turbinates, and airway widening. Parasympathetic stimulation causes opposite effects.

Located in the nasal mucosa are the mast cells, which participate in the regulation of nasal patency by releasing such mediators as histamine. These are described below.

IMMUNE RESPONSE TO ALLERGENS

2 Allergic reactions in the nose are mediated by antigen–antibody responses, during which allergens interact with specific IgE molecules bound to nasal mast cells and basophils. In allergic people, these cells are increased in both number and reactivity. During inhalation, airborne allergens enter the nose and are processed by lymphocytes, which produce antigen-specific IgE, thereby sensitizing genetically predisposed hosts to those agents. Upon nasal reexposure, IgE bound to mast cells interacts with airborne allergen, triggering release of inflammatory mediators (Fig. 104–1).[7]

Both immediate and late-phase reactions are observed after allergen exposure. The immediate reaction occurs within seconds to minutes, resulting in the rapid release of preformed mediators and newly generated mediators from the arachidonic acid cascade as the mast cell membrane is disturbed (Table 104–1). These mediators of immediate hypersensitivity include histamine; leukotrienes C_4, D_4, and E_4; prostaglandin D_2; tryptase; and kinins.[7] In addition, the mast cell has been found to be a source of several cytokines that probably are relevant to the chronicity of the mucosal inflammation that characterizes allergic rhinitis.[8] Sensory nerve stimulation produces itching, and sneezing occurs via reflex stimulation of efferent vagal

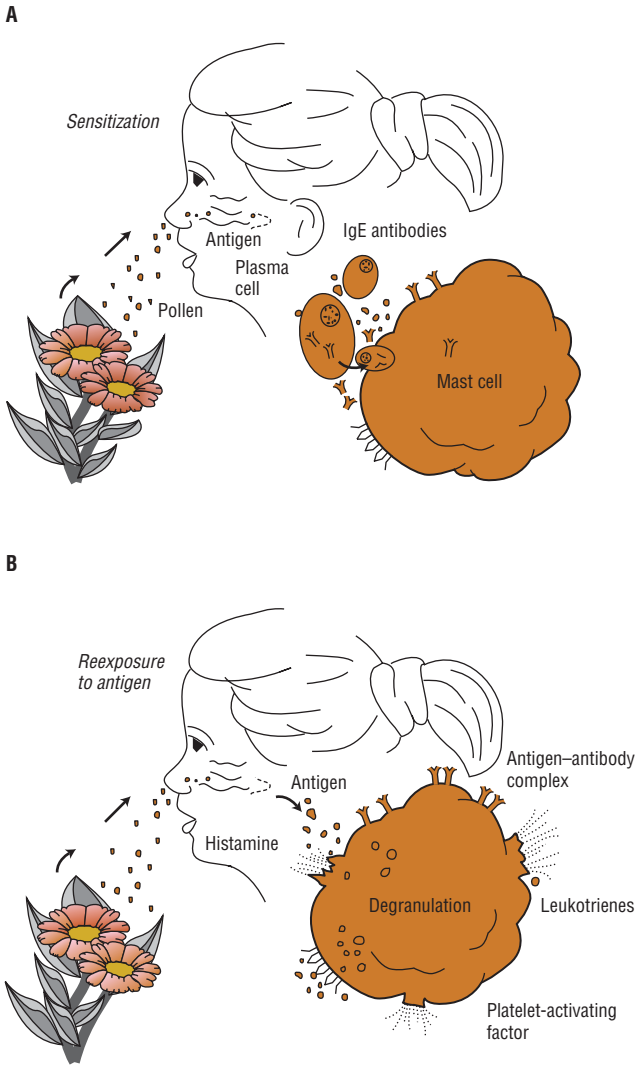

FIGURE 104-1. Allergen sensitization and the allergic response. (A) Exposure to antigen stimulates IgE production and sensitization of mast cells with antigen-specific IgE antibodies. (B) Subsequent exposure to the same antigen produces an allergic reaction when mast cell mediators are released.

TABLE 104-1 Mast Cell Mediators

Mediator	Effect
Preformed and rapidly released	
Histamine	Stimulates irritant receptors
	Pruritus
	Vascular permeability
	Mucosal permeability
	Smooth muscle contraction
Neutrophil chemotactic factor	Influx of inflammatory cells
Eosinophil chemotactic factor	Influx of inflammatory cells
Kinins	Vascular permeability
N-α-tosyl L-arginine methyl esterase	Vascular permeability
Newly generated	
Leukotrienes	Smooth muscle contraction
	Vascular permeability
	Mucus secretion
	Chemotaxis
	Neutrophil chemotaxis
Thromboxanes	Smooth muscle spasm
Platelet-activating factor	Mucus secretion
	Airway permeability
	Chemotaxis
	Vascular permeability

Heparin	Antiinflammatory
Tryptase	Protein hydrolysis
Kallikrein	Protein hydrolysis

pathways. Neuropeptides substance P and calcitonin gene-related peptide from nonadrenergic, noncholinergic nerves affect vascular engorgement directly and via modulation of sympathetic tone. Histamine produces rhinorrhea, itching, sneezing, and obstruction, with the obstruction only partially blocked by H_1- or H_2-blocking agents.[9] Nasal obstruction is also caused by kinins, prostaglandin D_2, and leukotrienes C_4/D_4. Kinins, when directly administered, produce pain rather than itching.[10] These inflammatory mediators also produce vasodilation, increased vascular permeability, and production of increased nasal secretions.[11]

Four to 8 hours after the initial exposure to an allergen, a late-phase reaction occurs symptomatically in 50% of allergic rhinitis patients.[12] This response, thought to be caused by cytokines released primarily by mast cells and thymus-derived helper lymphocytes, is characterized by profound infiltration and activation of migrating cells. This inflammatory response likely is responsible for the persistent, chronic symptoms of allergic rhinitis, including nasal congestion. The inflamed mucosa becomes hyperresponsive, a state characterized by exacerbation of nasal reactions to nonspecific or irritant triggers. In this state, the patient also reacts to increasingly lower amounts of the same allergen.[13] The process also causes significant increases in nonspecific irritability (as seen in asthma) and the notion among patients that they have become "allergic to everything."

CLINICAL PRESENTATION

SYMPTOMS AND DIAGNOSIS

The patient with allergic rhinitis typically complains of clear rhinorrhea, paroxysms of sneezing, nasal congestion, postnasal drip, and pruritic eyes, ears, nose, or palate. Symptoms of allergic conjunctivitis are associated more frequently with seasonal than perennial allergic rhinitis, because a majority of the perennial allergens, such as dust mites and molds, are indoors, where air velocity is too low for substantial deposition of allergenic particles on the conjunctivae. However, with heavy exposure from animal or mold allergens, allergic conjunctivitis can be pronounced.

Symptoms secondary to the late-phase reaction, predominantly nasal congestion, begin 3 to 5 hours after antigen exposure and peak at 12 to 24 hours. Subsequent symptoms, both allergic and irritant, are elicited more easily because of the priming effect. For instance, a ragweed-sensitive patient, when exposed to ragweed pollen out of season, responds with modest symptoms and may be very tolerant of irritants such as air pollution or tobacco smoke. During the ragweed season, however, when the nasal mucosa is already inflamed, exposure to small doses of pollen or to irritants to which the patient is usually tolerant elicits a response clinically indistinguishable from the patient's allergy.

Allergic rhinitis is distinguished from other causes of rhinitis by a thorough history, physical examination, and certain diagnostic tests. The medical history consists of a careful description of symptoms, environmental factors and exposures, results of previous therapy, use of other medications, previous nasal injuries, previous nasal or sinus surgery, family history, and the presence of other medical problems and medications. Historical identification of specific causative allergens may be difficult. For example, a reaction induced by mowing the lawn may not be caused by grass pollens but may be caused by the disturbance of various weeds, molds, or other plants in the lawn. With perennial allergic rhinitis, the cause–effect and temporal relationships are less clear, making the diagnosis of specific causes more difficult, especially with such covert allergens as house-dust mites and molds.

In children, physical examination may reveal allergic shiners—a transverse nasal crease caused by repeated rubbing of the nose—and adenoidal breathing. Pale, bluish, edematous nasal turbinates coated with thin, clear secretions are characteristic of a purely allergic reaction. Tearing, conjunctival injection and edema, and periorbital swelling may be present. Physical findings are generally less clear-cut for adults.

Nasal scrapings will provide a representative sample of cells infiltrating the nasal mucosa and can be helpful in supporting the diagnosis.[14] Microscopic examination of the nasal smear from an allergic individual typically will show numerous eosinophils. The blood eosinophil count may be elevated in allergic rhinitis, but it is nonspecific and has limited usefulness.[15]

Allergy testing can help determine whether a patient's rhinitis is caused by an allergen. Immediate-type hypersensitivity skin tests are used for the diagnosis of allergic rhinitis. These include skin tests performed by the percutaneous route, where the diluted allergen is pricked or scratched into the skin surface, or by the intradermal route, where a small volume (0.01 to 0.05 mL) of diluted allergen is injected between the layers of skin. Percutaneous tests are more commonly performed and are safer and more generally accepted, with intradermal tests reserved for patients requiring confirmation in special circumstances.

In all allergy testing, a positive control (histamine) and a negative control are essential for correct interpretation. After 15 minutes of the application of the allergen, the site is examined for a positive reaction (defined as a wheal-and-flare reaction). Because correct testing is done with extremely minute doses, undetectable by nonsensitized individuals, this reaction is evidence of the presence of mast cell-bound IgE specific to the allergen tested. Many, but not all, common allergens are available as standardized allergenic extracts.

Antihistamines and a few other medications interfere with the wheal-and-flare reaction. First-generation antihistamines should be stopped 3 to 5 days before testing, and second-generation, nonsedating antihistamines should be stopped for 10 days before testing.[16] Medications with antihistamine properties (e.g., sympathomimetic

agents, phenothiazines, and tricyclic antidepressants) should be discontinued before skin testing.

The radioallergosorbent test (RAST) was the first commonly used method for detecting IgE antibodies in the blood that are specific for a given allergen. Several other quantitative assays that include a reference curve calculated against standardized IgE are available. These tests are highly specific but may be slightly less sensitive than percutaneous tests.

CLINICAL PRESENTATION

General

- Allergic rhinitis occurs with exposure to allergens specific to a given patient. Intermittent symptoms occur with seasonal allergens such as pollens, and persistent symptoms occur with perennial allergens such as dust mites.

Symptoms

- The patient typically complains of clear rhinorrhea, paroxysms of sneezing, nasal congestion, postnasal drip, and pruritic eyes, ears, nose, or palate. Late-phase reaction consists of primarily nasal congestion.

Signs

- For children, physical exam may reveal allergic shiners, a transverse nasal crease caused by repeated rubbing of the nose, and adenoidal breathing. Nasal turbinates are coated with thin, clear secretions. Tearing and periorbital swelling may be present.

Laboratory

- Microscopic examination of the nasal smear will show numerous eosinophils. Blood eosinophil count may be elevated in allergic rhinitis, but it is nonspecific.

Other Diagnostic Tests

- Percutaneous skin tests with diluted allergen, positive control (histamine), and negative control are used to identify to what the patient has sensitivities. Also, a radioallergosorbant test can detect IgE antibodies in the blood that are specific for a given allergen.

COMPLICATIONS

Not only is allergic rhinitis aggravating, it also frequently leads to further complications, particularly if the patient does not receive adequate treatment. Symptoms of untreated rhinitis may lead to disturbed sleep, chronic malaise, fatigue, and poor work or school performance. Patients often are plagued by loss of smell or taste, with sinusitis or polyps underlying many cases of allergy-related hyposmia. Postnasal drip with cough, hoarseness, and even vocal polyps also can be bothersome.

The role of allergic rhinitis in the development of acute otitis media or chronic middle ear effusion is often less clear. Children with allergic rhinitis appear to be at greater risk of these conditions because of nasal obstruction and negative middle ear pressure. Hearing problems in children related to middle ear effusion may lead to delayed development of language in young children or to school problems in older children.

Structural facial and dental problems can result from chronic allergic rhinitis.[17,18] The chronic edema and venous stasis may contribute to the development of a high-arched, V-shaped palate. Mouth breathing caused by nasal obstruction can be responsible for dental malocclusion and orthodontic problems. Constant upward rubbing of the nose (allergic salute) can cause a transverse crease across the lower nose; nasal congestion often leads to venous pooling and dark circles under the eyes known as *allergic shiners*.

Allergic rhinitis is clearly a risk factor for asthma. The majority of asthma patients have nasal symptoms, whereas approximately 10% to 40% of rhinitis patients have asthma.[3] It is not known if allergic rhinitis is an early clinical manifestation of asthma or if the nasal disease itself is causative for asthma.

Recurrent sinusitis and chronic sinusitis are relatively common complications of allergic rhinitis. The structure of the mucus blanket breaks down, with decreased water production by serous glands, leaving hair cells trapped in the thicker mucus layer. This greatly reduces the clearance of trapped bacteria and offers ideal breeding grounds for the bacteria. Nasal polyps are less common but nonetheless bothersome; they require specific therapy but may improve with management of the underlying allergic state. Epistaxis also can be a problem; it is related to mucosal hyperemia and inflammation.

TREATMENT

Allergic Rhinitis

DESIRED OUTCOME

The therapeutic goal for patients with allergic rhinitis is to minimize or prevent symptoms and prevent long-term complications. This goal should be accomplished with no or minimal adverse medication effects and reasonable medication expenses. The patient should be able to maintain a normal lifestyle, including participating in outdoor activities, yard work, and playing with pets as desired.

GENERAL APPROACH TO TREATMENT

3 Once the causative allergens and the specific symptoms are identified, management consists of three possible approaches: (1) allergen avoidance, (2) pharmacotherapy for prevention or treatment of symptoms, and (3) specific immunotherapy. The pharmacotherapy for symptoms approach includes several options that are based on patient-specific information (Table 104–2). Figure 104–2 depicts an algorithm for treatment options.

AVOIDANCE

Avoidance of offending allergens is the most direct method of preventing allergic rhinitis, but it is often the most difficult to accomplish, especially for perennial allergens. Mold growth can be reduced by maintaining household humidity below 50% and removing obvious growth with bleach or disinfectant. Patients sensitive to animals will benefit most by removing pets from the home; however, most animal lovers are reluctant to comply with this approach. Dog and cat allergens may produce symptoms in sensitized individuals.[8] After removing a cat from the home, it may take as long as 20 weeks for the home to reach allergen levels of a pet-free home. Washing cats weekly may reduce allergens but studies are inconclusive.[8] Some dogs display antigens more profusely than do others; clinically, a sensitized person may tolerate one animal better than another.

Evidence to support avoidance measures for house dust mites suggests that accepted notions for reducing exposure have little practical effect.[19] While some evidence shows allergen levels can be reduced by washing bedding on a hot cycle, replacing carpets with hard flooring and using vacuum cleaners with HEPA filters, there is no documented evidence for a clinical benefit. Only encasing bedding in impermeable covers has some clinical benefit in children

TABLE 104-2 Pharmacotherapeutic Options for Allergic Rhinitis

Medication Class	Symptoms Controlled	Comments
Antihistamines		
Systemic	Sneezing, rhinorrhea, itching, conjunctivitis	For seasonal allergic rhinitis, begin treatment before allergen exposure. Nonsedating agents should be tried first. If ineffective or too expensive for the patient, the older agents may be used. For perennial allergic rhinitis, use an intranasal steroid as an alternative to or in combination with systemic antihistamines.
Ophthalmic	Conjunctivitis	Logical addition to nasal steroids if ocular symptoms are present.
Intranasal	Sneezing, rhinorrhea, nasal pruritus	Option for seasonal allergic rhinitis. Warn patients of potential drowsiness.
Decongestants		
Systemic	Nasal congestion	Only needed when nasal congestion is present.
Topical	Nasal congestion	Only needed when nasal congestion is present. Do not exceed 3–5 days.
Intranasal corticosteroids	Sneezing, rhinorrhea, itching, nasal congestion	For seasonal allergic rhinitis, an option when congestion is present. Must begin therapy before allergen exposure. Excellent choice for perennial rhinitis.
Mast cell stabilizers	See comments.	Prevents symptoms; therefore, for seasonal allergic rhinitis, use before offending allergen's season starts. For perennial rhinitis, improvement may not be seen for up to 1 month.
Intranasal anticholinergics	Rhinorrhea	Reserve for use when above therapies fail or cannot be tolerated.
Leukotriene receptor antagonists	See comments.	When combined with antihistamines, more effective than antihistamines alone. May be used as monotherapy in children with asthma and coexisting allergic rhinitis.

but not adults. Future studies are needed to determine if environmental control of allergens may be helpful in forestalling further rhinitis and preventing later asthma.

General recommendations have been made to prevent poor air quality in homes.[20] Steps include avoiding wall-to-wall carpeting, using moisture control to prevent the accumulation of molds, and controlling sources of pollution such as cigarette smoke. Patients with seasonal allergic rhinitis should keep windows closed and minimize time spent outdoors during pollen seasons. Immediate hair washing and change of clothes are recommended upon returning indoors. Use of fans that direct outside air into the house should be avoided. Filter masks can be worn while gardening or mowing the lawn. Avoidance of upholstery and stuffed toys in the bedroom are easy steps to accomplish. Table 104–3 summarizes recommendations for environmental control. While these steps are logical, there is little existing evidence that environmental control measures provide clinical benefit. These measures are intended to be a part of a comprehensive treatment strategy that will likely include pharmacotherapy and, in selected cases, immunotherapy.

PHARMACOLOGIC THERAPY

First-line therapeutic modalities for treating allergic rhinitis are directed at relief of symptoms (see Table 104–2). Antihistamines and decongestants (both oral and topical) generally are used first in treating allergic rhinitis with medications. Several options in these two categories are available without a prescription, but patients will need sound advice to make appropriate choices. Knowledge of pathophysiology and the inflammatory state has led to prophylactic therapy for those with more severe disease using agents such as cromolyn and topical steroids. However, in attempting to assess the evidence supporting any particular therapy, clinicians have difficulty interpreting the medical literature for a variety of reasons, including lack of uniformity in the research methodologies, inappropriate drug controls, and failure to identify types of rhinitis in study subjects (perennial versus seasonal and allergic versus nonallergic).

Antihistamines

Histamine (H_1)-receptor antagonists are competitive antagonists to histamine. They bind to H_1 receptors without activating them, preventing histamine binding and action. Second-generation antihistamines may also affect components of the inflammatory response such as histamine release, generation of adhesion molecules, and influx of inflammatory cells. Although it was once thought that the older antihistamines had no antiinflammatory action, some were shown to have these effects as early as the 1950s.[21] Antihistamines are available in oral, ophthalmic, and intranasal dosage forms.

The oral antihistamines are the most commonly used and can be divided into two major categories: nonselective (first generation) and peripherally selective (second generation). Nonselective agents are commonly referred to as *sedating antihistamines*, and peripherally selective agents are referred to as *nonsedating antihistamines*. These generalizing terms can be misleading. Individual agents should be judged on their specific characteristics because variation within these broad categories exists. Also, the nonsedating claim is only valid when the agents are used at recommended doses.[22] This is of particular concern as some of these antihistamines are available without a prescription. The mechanism for sedation is not well understood, but its central effect depends on the drugs' ability to cross the blood–brain barrier. Most older antihistamines are lipid soluble and cross this barrier easily. The peripherally selective agents have little or no central or autonomic nervous system effects. Table 104–4 lists common antihistamines, their chemical classifications, their relative potential for causing sedation, and their relative anticholinergic effects.

Antihistamines are much more effective in preventing the actions of histamines than in reversing these actions once they have taken place. Reversal of symptoms is largely caused by the anticholinergic properties of these drugs. This activity is responsible for the drying effect of antihistamines, which reduces the problem of nasal, salivary, and lacrimal gland hypersecretion. Antihistamines antagonize increased capillary permeability, wheal-and-flare formation, and itching.

In general, the antihistamines are well absorbed, have large volumes of distribution, and are metabolized by the liver. Serum half-lives vary considerably between patients. In addition, the therapeutic effects of these agents are more prolonged than might be predicted by their half-lives.

Drowsiness is usually the chief complaint of patients who take antihistamines. It can interfere with a patient's ability to drive a car or operate machinery and may interfere with the patient's ability to function adequately at the workplace. Remember that these problems can also be a reflection of the disease itself. For this reason, many recommend the use of peripherally selective agents as first-line treatment for any patient who is at high risk

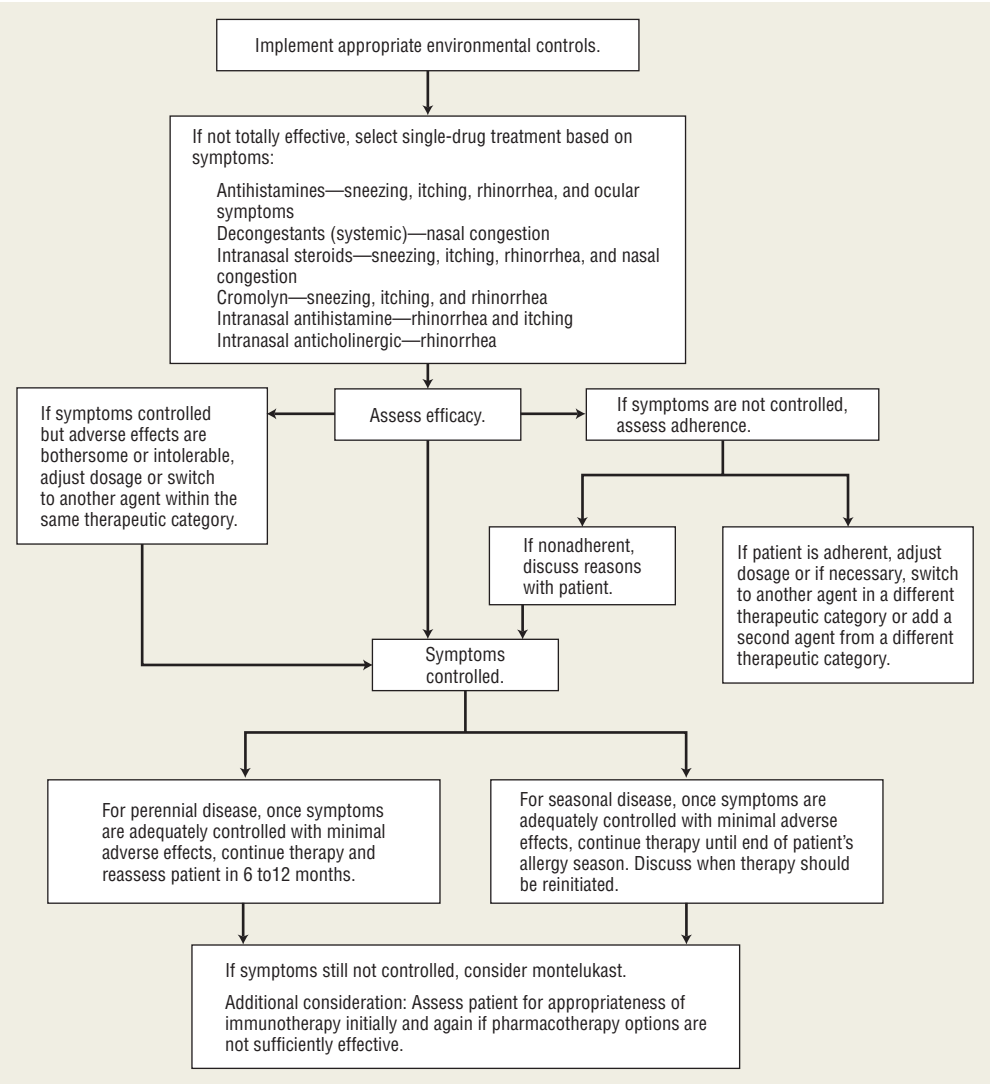

FIGURE 104-2. Treatment algorithm for allergic rhinitis.

for the development of adverse events. This includes patients with renal or hepatic impairment, those with small weights (for whom adult doses may provide larger-than-recommended doses on a milligram-per-kilogram basis), patients with preexisting central-nervous-system or cardiac disorders, patients who require higher doses, and patients who have shown a tendency to overuse nonprescription or prescription medications.[21]

The sedative effects of antihistamines can be useful for patients who suffer from sleeplessness caused by the symptoms of allergic rhinitis. In these patients, a bedtime dose may prove beneficial. However, they may cause residual daytime sedation, decreased alertness, and performance impairment.

The logic of preferentially using the second-generation agents is not clear-cut. A metaanalysis of performance-impairment trials did not show a clear and consistent distinction between diphenhydramine and the peripherally selective agents.[23] Another study showed that tolerance to sedation secondary to diphenhydramine developed by day 4 of treatment, becoming indistinguishable from placebo,[24] but sedation must be distinguished from impairment since the two are not equivalent.

Anticholinergic (drying) effects contribute to the agents' therapeutic efficacy, but they also cause most adverse effects. Dry mouth, difficulty in voiding urine, constipation, and potential cardiovascular effects may be troublesome. Keep in mind that the differences may be small. Patients with a predisposition to urinary retention (e.g., older men and those on concurrent anticholinergic therapy) should use antihistamines with caution. Caution also should be used for patients with increased intraocular pressure, hyperthyroidism, and cardiovascular disease.

Other adverse effects of oral antihistamines include loss of appetite (and paradoxically, weight gain with increased appetite), nausea, vomiting, and epigastric distress.

Antihistamines are only fully effective when taken approximately 1 to 2 hours before anticipated exposure to the offending allergen. This must be discussed with patients who face exposure daily during a pollen season and with those who have indoor perennial allergens where daily scheduled use is necessary. If tolerance develops to the therapeutic effect, a change to an agent in a different chemical class is usually effective.

Patients should be counseled about the proper use of antihistamines. Adverse effects, especially drowsiness, should be emphasized. Patients should be warned against taking other central-nervous-system depressants, including the use of alcohol. Patients should be told not to take a double dose when a dose is missed. Taking the antihistamine with meals or at least a full glass of water will help prevent gastrointestinal adverse effects such as nausea, vomiting, and epigastric distress. Patients should check with their healthcare professional and read labels before taking nonprescription medications. Many cold products and sleep aids contain antihistamines. Patients should be instructed not to use

TABLE 104-3 Environmental Controls to Prevent Allergic Rhinitis

Pollens
- Keep windows and doors closed during pollen season
- Avoid fans that draw in outside air
- Use air conditioning
- If possible, eliminate outside activities during times of high pollen counts
- Shower, shampoo, and change clothes following outdoor activity
- Use a vented dryer rather than an outside clothesline

Molds
- Use similar controls as above
- Avoid walking through uncut fields, working with compost or dry soil, and raking leaves
- Clean indoor moldy surfaces
- Fix all water leaks in home
- Reduce indoor humidity to <50% if possible

House-dust mites
- Encase mattress, pillow, and box springs in an allergen-impermeable cover
- Wash bedding in hot water weekly
- Remove stuffed toys from bedroom
- Minimize carpet use and upholstered furniture
- Reduce indoor humidity to <50% if possible

Animal allergens (if removal of pet is not acceptable)
- Keep pet out of patient's bedroom
- Isolate pet from carpet and upholstered furniture
- Wash pet weekly

Cockroaches
- Keep food and garbage in tightly closed containers
- Take out garbage regularly
- Clean up dirty dishes promptly
- Use roach traps

Other recommendations
- Do not allow smoking around the patient, in the patient's house, or in the family car
- Minimize the use of wood-burning stoves and fireplaces

Adapted from reference 3.

TABLE 104-4 Relative Adverse-Effect Profiles of Antihistamines

Medication	Relative Sedative Effect	Relative Anticholinergic Effect
Alkylamine class, nonselective		
Brompheniramine maleate	Low	Moderate
Chlorpheniramine maleate	Low	Moderate
Dexchlorpheniramine maleate	Low	Moderate
Ethanolamine class, nonselective		
Carbinoxamine maleate	High	High
Clemastine fumarate	Moderate	High
Diphenhydramine hydrochloride	High	High
Ethylenediamine class, nonselective		
Pyrilamine maleate	Low	Low to none
Tripelennamine hydrochloride	Moderate	Low to none
Phenothiazine class, nonselective		
Promethazine hydrochloride	High	High
Piperidine class, nonselective		
Cyproheptadine hydrochloride	Low	Moderate
Phenindamine tartrate	Low to none	Moderate
Phthalazinone class, peripherally selective		
Azelastine (nasal only)	Low to none	Low to none
Piperazine class, peripherally selective		
Cetirizine	Low to moderate	Low to none
Levocetirizine	Low to moderate	Low to none
Piperidine class, peripherally selective		
Desloratadine	Low to none	Low to none
Fexofenadine	Low to none	Low to none
Loratadine	Low to none	Low to none

more than one antihistamine at a time. Table 104–5 lists the recommended dosages of the commonly used agents with their prescription status.

Many patients respond to and tolerate the older agents quite well. Because many of the older agents are available generically, they are much less expensive. Patient cost for many of the older nonprescription agents is less than $5 for a 30-day supply, compared with more than $20 for some of the nonprescription selective agents and more than $70 dollars for the selective prescription-only products. Although cost is a concern, patient safety should be the first consideration. Interestingly, the most frequently recommended nonprescription antihistamine to adults by pharmacists was diphenhydramine.[25] This may be because the use of diphenhydramine as a sleep aid. With the heavy promotion of competing brands of nonprescription loratadine, this ranking may change. Loratadine in combination with pseudoephedrine did show up in the same survey as the top pharmacists' pick in the "adult multi-symptom allergy" category. The over-the-counter availability of cetirizine further broadens the range of suggestions.

For seasonal and perennial allergic rhinitis, an intranasal antihistamine, azelastine, is available. The 0.1% product can be used in children and is effective in seasonal allergies, while the 0.15% product is used in adults only and may be used for either type of allergic rhinitis. Azelastine has been used successfully for patients who did not respond to loratadine.[26] Using the nasal route offers an alternative to switching to another oral antihistamine. Patient satisfaction has been varied because while the product produces rapid symptom relief, patients complain of drying effects, headache, and diminished effectiveness over time. Patients should be warned of the medication's potential to produce drowsiness, as its systemic availability is approximately 40%.[27,28]

Allergic conjunctivitis, often associated with allergic rhinitis, can be treated with an ophthalmic antihistamine such as levocabastine. Because systemic antihistamines usually are also effective for allergic conjunctivitis, levocabastine is a logical addition to nasal steroids when ocular symptoms occur, and it is an acceptable approach for patients whose only symptoms involve the eyes or to add for those whose symptoms persist on oral treatment.

CLINICAL CONTROVERSY

Although many clinicians strongly prefer a peripherally selective agent as the first antihistamine choice, economic considerations still result in the first-line choice of the less expensive and more sedating products by some prescription plans and clinicians.

Decongestants

Topical and systemic decongestants are sympathomimetic agents that act on adrenergic receptors in the nasal mucosa, producing vasoconstriction. Decongestants shrink swollen mucosa and improve ventilation. When nasal congestion is part of the clinical picture, decongestants work well in combination with antihistamines.

TOPICAL DECONGESTANTS

Topical decongestants are applied directly to swollen nasal mucosa via drops or sprays. Table 104–6 lists the common topical decongestants and their durations of action. The use of these agents results in little or no systemic absorption.

TABLE 104-5 Oral Dosages of Commonly Used Oral Antihistamines and Decongestants

Medication	Availability	Dosage and interval[a]	
		Adults	***Children***
Nonselective (first-generation) antihistamines			
Chlorpheniramine maleate, plain[b]	OTC	4 mg every 6 h	6–12 y: 2 mg every 6 h 2–5 y: 1 mg every 6 h
Chlorpheniramine maleate, sustained-release	OTC	8–12 mg daily at bedtime or 8–12 mg every 8 h	6–12 y: 8 mg at bedtime <6 y: Not recommended
Clemastine fumarate[b]	OTC	1.34 mg every 8 h	6–12 y: 0.67 mg every 12 h
Diphenhydramine hydrochloride[b]	OTC	25–50 mg every 8 h	5 mg/kg per day divided every 8 h (up to 25 mg per dose)
Peripherally selective (second-generation) antihistamines			
Loratadine[b]	OTC	10 mg once daily	6–12 y: 10 mg once daily 2–5 y: 5 mg once daily
Fexofenadine	Rx	60 mg twice daily or 180 mg once daily	6–11 y: 30 mg twice daily
Cetirizine[b]	OTC	5–10 mg once daily	>6 y: 5 mg once daily Infants 6–11 month[c]
Levocetirizine	Rx	5 mg every evening	6–11 y: 2.5 mg every evening
Oral decongestants			
Pseudoephedrine, plain[b]	OTC[e]	60 mg every 4–6 h	6–12 y: 30 mg every 4–6 h 2–5 y: 15 mg every 4–6 h
Pseudoephedrine, sustained-release[d]	OTC[e]	120 mg every 12 h	Not recommended
Phenylephrine[f]	OTC	10–20 mg every 4 h	6–12 y: 10 mg every 4 h 2–6 y: 0.25% drops, 1 mL every 4 h

OTC, nonprescription; Rx, prescription.
[a]Dosage adjustment may be needed in renal/hepatic dysfunction. Refer to manufacturers' prescribing information.
[b]Available in liquid form.
[c]0.25 mg/kg orally demonstrated to be safe.[31]
[d]Controlled-release product available: 240 mg once daily (60-mg immediate-release with 180-mg controlled-release).
[e]See text regarding nonprescription requirements.
[f]Phenylephrine has replaced pseudoephrine in many nonprescription antihistamine–decongestant combination products. Read product labels carefully.

Because these agents are extremely effective and are available to patients without a prescription, they are widely used. However, prolonged use of these agents (for more than 3 to 5 days) can result in a condition known as *rhinitis medicamentosa*, or *rebound vasodilation*, with even more severe congestion. Patients who develop this condition use increasingly more spray more often with less response. Although the methods used to treat this "addiction" have not been studied formally, several are used commonly. Abrupt cessation works, but it is difficult because of rebound congestion that may leave the patient congested for several days or weeks. Sleeping may become difficult. Nasal steroids have been used successfully, but they take several days to work. Weaning the patient off topical decongestants can be accomplished by decreasing the dosing frequency or the concentration over several weeks. Combining the weaning process with nasal steroids may prove useful. Ultimately, the success of any plan depends on the patient's resolve and clear understanding of the importance of stopping the drug to end the problem.

Other adverse effects of topical decongestants include burning, stinging, sneezing, and dryness of the nasal mucosa.

TABLE 104-6 Duration of Action of Topical Decongestants

Medication	Duration (h)
Short acting	
Phenylephrine hydrochloride	Up to 4
Intermediate acting	
Naphazoline hydrochloride Tetrahydrozoline hydrochloride	4–6
Long acting	
Oxymetazoline hydrochloride Xylometazoline hydrochloride	Up to 12

Patients should be counseled on the use of topical decongestants to prevent rhinitis medicamentosa. Patients should be instructed to use as small a dose as possible as infrequently as possible and only when absolutely necessary (e.g., at bedtime to aid in falling asleep). Duration of therapy always should be limited to 3 to 5 days.

Systemic Decongestants

Oral decongestants are not as effective on an immediate basis as the topical agents, but their effects sometimes last longer and they cause less local irritation. In addition, rhinitis medicamentosa is not a problem with oral agents. The most commonly used agent is pseudoephedrine. Table 104–5 lists the usual doses for the regular and sustained-release versions. The use of phenylephrine is increasing because of new regulations related to pseudoephedrine described below.

Concerns of safety have greatly limited the systemic decongestant options. Legal requirements for the sale of pseudoephedrine were put into place to combat the misuse of the drug as a component in making methamphetamine. Pseudoephedrine must now be sold behind the counter, and the monthly amount a patient can purchase is limited. Until this requirement, pseudoephedrine was the most frequently used systemic decongestant, and it was considered the safest. Doses of 180 mg have been shown to produce no measurable change in blood pressure or heart rate.[29] In higher doses (210 to 240 mg), pseudoephedrine has raised both blood pressure and heart rate.[30] Pseudoephedrine can cause mild central-nervous-system stimulation, even at therapeutic doses. Stroke, related to use of oral decongestants such as pseudoephedrine, can occur in patients with hypertension and/or vasospasm.[31] Although stroke complications seem to be associated with higher-than-recommended doses, there is also a stroke risk when these agents are taken properly. Severe hypertensive reactions can occur when pseudoephedrine is given concomitantly with monoamine

TABLE 104-7 Dosage of Nasal Steroids

Medication	Dosage and Interval
Beclomethasone dipropionate, monohydrate	>12 y: 1–2 inhalations (42–84 mcg) twice daily in each nostril 6–12 y: 1 inhalation per nostril (42 mcg) twice daily to start
Budesonide	>6 y: 2 sprays (64 mcg) per nostril in am and pm or 4 sprays per nostril in am (maximum: 256 mcg)
Flunisolide	Adults: 2 sprays (50 mcg) per nostril twice daily (maximum: 400 mcg) Children: 1 spray per nostril three times a day
Fluticasone	Adults: 2 sprays (100 mcg) per nostril once daily; after a few days decrease to 1 spray per nostril Children >4 y and adolescents: 1 spray per nostril once daily (maximum: 200 mcg/day)
Mometasone furoate	>12 y: 2 sprays (100 mcg) per nostril once daily
Triamcinolone acetonide	>12 y: 2 sprays (110 mcg) per nostril once daily (maximum: 440 mcg/day)

oxidase inhibitors.[32] Hypertensive patients should, unless necessary, avoid systemic decongestants.

Combination Products

Numerous products combine an antihistamine with a decongestant. While the combination may be rational because of the different mechanisms of action, remember that antihistamines must be taken on a regular schedule, but decongestants should only be used when needed. Both nonselective and peripherally selective antihistamines are available in such combinations. As mentioned previously, patients should read labels to avoid therapeutic duplication. Consideration should be given to how often the patient is congested before recommending these combinations.

NASAL STEROIDS

Nasal steroids are an excellent choice for treating perennial rhinitis, and can be useful in seasonal rhinitis, especially if begun in advance of symptoms. Nasal steroids appear to be effective with minimal adverse effects. Some believe that nasal steroids should be recommended as initial therapy over antihistamines because of their high level of efficacy when used properly and along with avoidance of allergens.[8] Multiple mechanisms are involved with the effects of nasal steroids on the nasal mucosa: reducing inflammation by reducing mediator release, suppressing neutrophil chemotaxis, reducing intracellular edema, causing mild vasoconstriction, and inhibiting mast cell-mediated late-phase reactions. Table 104–7 lists the available nasal steroids and their usual doses.

Topical steroids produce only minor adverse effects, most commonly sneezing, stinging, headache, and epistaxis. Despite concerns about safety of systemic steroids, nasal steroids have been found to have no significant association with hypothalamic–pituitary axis suppression, cataract formation, glaucoma, or bone mineral density changes in the doses used for allergic rhinitis. Growth suppression remains a question with some evidence showing that nasal steroids with higher bioavailability (e.g., beclomethasone) may have a greater growth-suppression effect than less bioavailable agents.[33] These findings require more study. Most likely, all currently available nasal steroids are safe in the majority of patients, and their clinical benefits outweigh any small growth suppressive effect. Other concerns include local infections with *Candida albicans*, which occur rarely.

The therapeutic benefits of topical steroids are not immediate, and they are not decongestants. Patients need to understand this to ensure cooperation and continuation of therapy. Some patients notice improvement in a few days, but peak responses may not be observed for 2 to 3 weeks. Once a response is achieved, the dosage may be reduced. Blocked nasal passages should be cleared with a decongestant or saline irrigation before administration to ensure adequate penetration of the spray. Patients should be advised to avoid sneezing or blowing their noses for at least 10 minutes after administration. Topical steroids should not be used for patients with nasal septum ulcers or recent nasal surgery or trauma.

One additional benefit of nasal steroids in treating allergic rhinitis in individuals with asthma and upper airway conditions is that they may confer some protection against exacerbations of asthma, leading to fewer emergency room visits. The overall relative risk for an emergency visit among asthma patients who received intranasal steroids was 0.7.[34] No effect was seen for patients receiving antihistamines.

OTHER INHALANT MEDICATIONS

Cromolyn sodium and ipratropium bromide offer two additional approaches for treating allergic rhinitis. Cromolyn sodium is a mast cell stabilizer. Increased interest in this product has resulted from it becoming available without a prescription. Ipratropium bromide is an anticholinergic agent useful in perennial allergic rhinitis.

Cromolyn sodium nasal spray is used for the symptomatic prevention and treatment of allergic rhinitis. It curtails antigen-triggered mast cell degranulation and release of the mediators of allergic reactions, including histamine. Cromolyn sodium has no direct antihistaminic, anticholinergic, or antiinflammatory properties. Similarly to topical steroids, the most common adverse effects—sneezing and nasal stinging—result from local irritation. The dose in adults and children at least 2 years of age is one spray in each nostril three to four times per day at regular intervals every 4 to 6 hours. Cromolyn sodium must cover the entire nasal lining; therefore, patients should be instructed to clear nasal passages before administration. Inhaling gently through the nose during administration aids in this process. Dosing must be repeated at 6-hour intervals to maintain the effect.

For seasonal rhinitis, treatment with cromolyn sodium should be initiated just before the usual start of the offending allergen's season and continued throughout the season. In perennial rhinitis, the effects may not be seen for 2 to 4 weeks; therefore, antihistamines or decongestants may be needed during this initial phase of therapy. As cromolyn sodium begins to work, the need for these medications should decrease.

Ipratropium nasal spray is an anticholinergic agent that exhibits antisecretory properties when applied locally. It provides symptomatic relief of rhinorrhea associated with allergic and other forms of chronic rhinitis. The 0.03% solution is given as two sprays (42 mcg) two to three times daily. The optimal dose should be determined based on the specific patient's symptoms and response. Adverse effects are mild, with the most common being headache, nosebleeds, and nasal dryness.

IMMUNOTHERAPY

4 The first report of the successful use of grass pollen extract injections to treat allergic rhinitis was published in 1911 by Noon.[35] The therapy was first called *desensitization*; however, this did not seem appropriate because skin reactivity sometimes remained. The name was later changed to *hyposensitization*. Although this term is still used today, *immunotherapy* is used more commonly and is less confusing.

Immunotherapy is the slow, gradual process of injecting increasing doses of antigens responsible for eliciting allergic symptoms into a patient with the hope of inducing tolerance to the allergen

when natural exposure occurs. Several mechanisms have been proposed to explain the beneficial effects of immunotherapy, including induction of IgG-blocking antibodies, reduction in specific IgE (long-term), reduced recruitment of effector cells, altered T-cell cytokine balance (a shift from T-helper type 1 to T-helper type 2), T-cell anergy, and induction of regulatory T cells.[36]

Immunotherapy is moderately expensive, has significant potential risks, and requires a major time commitment from the patient. However, the cost of immunotherapy is usually covered by insurance, including Medicaid. Long-term savings can be realized since decades of treatment with medication can be averted through successful immunotherapy. Candidates for immunotherapy should have significant symptoms unsuccessfully controlled by avoidance and pharmacotherapy or should stand to benefit in other significant ways, such as with asthma. Immunotherapy may postpone the onset of asthma or possibly even prevent it.[37] Patients who are unable to tolerate the adverse effects of properly managed drug therapy also should be considered. Patients must be committed to the necessary regular office visits required to complete this course of therapy over several years.

The effectiveness of immunotherapy for seasonal allergic rhinitis appears to be better than that seen with perennial rhinitis, in part because it is more difficult to determine which allergen is responsible for perennial symptoms, and it is more often due to multiple sensitizations. Effectiveness has been shown in a number of clinical studies using a variety of pollen extracts, even for patients with severe disease resistant to pharmacotherapy.[36] Specific immunotherapy for house-dust mites has had good results in appropriately selected patients, while several studies have described marked improvement for patients with allergy to cats. Data indicate that for some patients 3 years of immunotherapy may be sufficient to give lasting benefit;[38] however, many require longer treatment.

The selection of antigens should be based on patient history and skin test results. Numerous regimens for administration of selected allergens have been suggested. In the beginning, very dilute solutions are given initially one to two times per week. The concentration is increased until the maximum tolerated or highest planned or effective dose is achieved. This maintenance dose is continued in slowly increasing intervals over several years, depending on clinical response. In light of the present understanding of the immunologic results of immunotherapy, it should be given year-round rather than seasonally.

Adverse reactions can occur with immunotherapy and range from mild to life threatening. Among the most common are mild local reactions, consisting of induration and swelling at the site of the injection. These may be immediate or delayed. Other more serious reactions (e.g., generalized urticaria, bronchospasm, laryngospasm, and vascular collapse) occur rarely; deaths can result from anaphylactic reactions. Severe reactions are treated with epinephrine as well as other modalities recommended for anaphylaxis. Because of this potential risk, immunotherapy must not be given without adequate direct observation in a medical facility.

Several patient types have been identified as poor candidates for immunotherapy, including patients with any medical condition that would compromise the ability to tolerate an anaphylactic-type reaction, patients with impaired immune systems, and patients with a history of nonadherence to therapy.[39]

LEUKOTRIENE RECEPTOR ANTAGONISTS

Leukotriene receptor antagonists inhibit the cysteinyl leukotriene receptor. The cysteinyl leukotrienes are one type of inflammatory mediators released from mast cells in allergy. Montelukast is approved for the treatment of perennial allergic rhinitis in children as young as 6 months and for seasonal allergic rhinitis in children as young as 2 years. Montelukast is effective alone or in combination with an antihistamine.[8]

TABLE 104-8 Dosage Regimens for Montelukast in Treatment of Allergic Rhinitis

Age	Dosage
Adults and adolescents >14 years	10 mg tablet daily
Children 6–14 years	5 mg chewable tablet daily
Children 6 months to 5 years	4 mg chewable tablet or oral granule packet daily

Studies published to date show leukotriene receptor antagonists to be no more effective than peripherally selective antihistamines and less effective than intranasal steroids. However, when combined with antihistamines, they are more effective than the antihistamine alone.[40] In children with mild persistent asthma and coexisting allergic rhinitis, montelukast as monotherapy has been recommended.[41] Table 104–8 lists dosage regimens.

CLINICAL CONTROVERSY

The exact role of montelukast in treating allergic rhinitis remains to be defined. Although expensive, it may be advantageous in men with significant prostatic hypertrophy who can not tolerate antihistamines and for patients who have difficulty stopping antihistamines a week before skin testing.

ALTERNATIVE TREATMENT OPTIONS

The development of monoclonal antibodies directed against the binding site of IgE provides an additional way to treat allergic respiratory diseases. Omalizumab, a recombinant humanized anti-IgE monoclonal antibody, is the first to show efficacy in allergic rhinitis.[42] The actual mechanism of how this agent is thought to work is quite complex.[43] Anti-IgE antibodies bind to the site on the IgE molecule that recognizes the IgE receptor, thereby preventing the IgE molecule from binding to mast cells or basophils. The half-life of IgE antibodies on the mast cell surface is about 6 weeks, and as the antibodies turn over, they become available for binding to anti-IgE antibodies. Thus by giving repeated doses of omalizumab, the number of IgE antibodies on the mast cell surface can be significantly reduced over time. These new IgE molecules are not eliminated but remain in circulation as small immune complexes. IgE receptor numbers on basophils and mast cells may be decreased as a result of downregulation. Because of the extremely expensive nature of this therapy, omalizumab's role strictly limited to allergic asthma.

CLINICAL CONTROVERSY

Omalizumab may offer significant long-term benefits to allergic rhinitis patients, but it may prove to be too expensive to gain widespread acceptance.

As mentioned earlier in this chapter, microbial exposure in the early years of life could help prevent allergic disease by favoring a nonatopic immune response.[5] This concept was further studied by administering *Lactobacillus rhamnosus* prenatally to mothers who had at least one first-degree relative or partner with atopic disease (eczema, allergic rhinitis, or asthma) and postnatally for 6 months to their infants.[44] However, their use may be limited to treatment or

prevention of childhood eczema as available evidence shows little benefit in allergic airway diseases.[45]

Other avenues for treating allergic rhinitis include Chinese herbal medicine and acupuncture. Although study designs and the small number of patients included have been questioned, these treatments deserve further study.[46]

PHARMACOECONOMIC CONSIDERATIONS

The economic impact of allergic rhinitis is enormous. The direct costs have grown significantly over the past few years because of the increasing use of peripherally selective antihistamines and nasal steroids. The most recent review of the annual costs of allergic rhinitis in the United States has been estimated at $2 billion and $5 billion.[47] In an older study detailing drug use in allergic rhinitis, 51% of prescribed agents were peripherally selective antihistamines, 25% intranasal steroids, and 5% older antihistamines.[48] A total of 58% of patients received one or more agents. The mean prescription medication expenditure was $103 per patient for those on Medicaid, $155 for patients with private insurance, and $69 for patients with no insurance. Estimates of work productivity losses ranged from $2.4 billion to $4.6 billion.[49] Direct-to-consumer advertising for prescription-only allergic rhinitis treatment options has also increased significantly. How this will affect the prescription market is unknown.

The most cost-effective choice of treatment for allergic rhinitis is an individualized decision. Seasonal allergic rhinitis patients who see improvement and can tolerate nonprescription and/or generic antihistamines will experience the least impact on out-of-pocket medical and drug expenses. If these are ineffective, the economic picture becomes more complicated. Choices should follow the logical path based on symptoms, tolerance, and efficacy, as described earlier in this chapter. Knowledge of an individual patient's drug coverage or lack of drug coverage may drive drug choices.

EVALUATION OF THERAPEUTIC OUTCOMES

With allergic rhinitis, major outcomes include the effect of the disease on a patient's life, the efficacy and tolerability of treatment, and patient satisfaction. Consideration must be given to how the condition is affecting the patient's job or school performance, family and social interactions, and other aspects of quality of life. The drug therapy should prevent or minimize symptoms with minimal or no adverse effects. The patient should not have difficulty obtaining needed medication for financial or other reasons. Patients should be questioned about their satisfaction with the management of their allergic rhinitis. The management should result in minimal disruption to their lives.

Both the Medical Outcomes Study 36-Item Short Form Health Survey and the Rhinoconjunctivitis Quality of Life Questionnaire have been used to evaluate outcomes of treatment for seasonal and perennial allergic rhinitis.[47–49] These tools go beyond measuring improvement in symptoms and include such items as sleep quality, nonallergic symptoms (e.g., fatigue, poor concentration, and others), emotions, and participation in a variety of activities. How well each of the current treatment modalities performs and how they compare in improving patient outcomes remain to be determined.

Clinicians caring for allergic rhinitis patients should develop a comprehensive pharmaceutical care plan that addresses several areas. Discuss and agree on therapeutic end points for allergic rhinitis, including the patient's acceptable level of symptom relief, onset of symptom relief expectations, and seasonal starts and stops. Discuss adverse drug reaction self-monitoring and prevention based on treatment selection. Assess patient attitude toward adherence to and persistence with oral, ocular, intranasal, or immunologic therapies. Ensure proper matching of treatment to symptoms and intervene with the prescriber if necessary. Conduct seasonal or annual review with patient.

The therapeutic goal for all patients with allergic rhinitis is to minimize or prevent symptoms. Evaluation of success is accomplished primarily through the discussions with the patient, in whom both relief of symptoms and tolerance of drug therapy must be discussed.

CONCLUSIONS

Allergic rhinitis is a common disease with symptoms ranging from mild to severe. If avoidance measures are unsuccessful, it should be treated to improve quality of life and prevent long-term complications. Timing of treating is essential. Treatment regimens should be individualized based on patient symptoms and response. Care should be taken to correctly identify allergy as the cause of the patient's rhinitis before committing them to chromic treatment.

ABBREVIATION

IgE: immunoglobulin E

SECTION 14
DERMATOLOGIC DISORDERS

CHAPTER 105

Dermatologic Drug Reactions and Common Skin Conditions

REBECCA M. LAW AND DAVID T.S. LAW

KEY CONCEPTS

1. The skin is the largest organ of the human body. It performs many vital functions such as (a) protecting the body against injury, physical agents, and UV radiation; (b) regulating body temperature; (c) preventing dehydration, thus helping to maintain fluid balance; (d) acting as a sense organ; and (e) acting as an outpost for immune surveillance. Skin also has a role in vitamin D production and absorption.
2. There are age-related factors affecting the epidermis and dermis. Pediatric skin is thinner and better hydrated, which enhances topical drug absorption and potential drug toxicities. Elderly skin is drier, thinner, and more friable, which may predispose to external insults.
3. Patients presenting with a skin condition should be interviewed thoroughly regarding signs and symptoms, urgency, medication history, etc. The skin eruption should be carefully assessed to help distinguish between a disease condition and a drug-induced skin reaction.
4. Drug-induced skin reactions can be irritant or allergic in nature.
5. Allergic drug reactions can be classified into exanthematous, urticarial, blistering, and pustular eruptions. Exanthematous reactions include maculopapular rashes and drug hypersensitivity syndrome. Urticarial reactions include urticaria, angioedema, and serum sickness-like reactions. Blistering reactions include fixed drug eruptions, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Pustular eruptions include acneiform drug reactions and acute generalized exanthematous pustulosis. There are other drug-induced skin reactions including hyperpigmentation and photosensitivity.
6. Not all skin reactions are drug-induced.
7. Contact dermatitis is a common skin disorder caused either by an irritant or an allergic sensitizer.
8. The first goal of therapy in the management of contact dermatitis involves identification, withdrawal, and avoidance of the offending agent. A thorough history, including work history, must be carefully reviewed for potential contactants.
9. Other goals of therapy for contact dermatitis include providing symptomatic relief, implementing preventative measures, and providing coping strategies and other information for patients and caregivers.
10. Diaper dermatitis is most often seen in infants although the condition may also be seen in older adults who wear diapers for incontinence. Management includes frequent diaper changes, air drying, gentle cleansing, and the use of barriers.
11. Skin cancers include squamous cell carcinoma, basal cell carcinoma, and malignant melanoma.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Skin is an essential part of our body. Although it is not commonly thought of as such, skin is an organ. In fact, it is the human body's largest organ, with an average surface area of about 1.8 m^2.[1] The organ system that includes our skin is known as *the integumentary system*.

The human skin consists of an outer epidermis and an inner dermis. The epidermis primarily provides protection from the environment and performs a critical barrier function—keeping water and other vital substances in and foreign elements out. The dermis is a connective tissue layer that primarily provides resiliency and support for various skin structures or appendages such as sweat glands, sebaceous glands, hair, and nails.

Since the skin surface is such a visible part of our body, changes that are slow or subtle often go unnoticed. Slowly enlarging and evolving moles or dry skin conditions can go undetected, even though such changes can be life threatening in some cases (e.g., malignancy). Health professionals who have direct contact with patients should be able to distinguish between common self-treatable skin lesions and common skin lesions that must be seen and treated professionally, such as melanoma or squamous cell carcinoma.

Skin infections and infestations are not covered in this chapter but are discussed in Chap. 119. Acne, psoriasis, and atopic dermatitis are discussed in Chaps. 106–108.

STRUCTURE AND FUNCTIONS OF THE SKIN

The integumentary system comprises the epidermis and dermis. The epidermis, which is derived from ectoderm, is further divided into four layers: *stratum basale* (basal layer), *stratum spinosum* (prickle cell layer), *stratum granulosum* (granular layer), and *stratum corneum* (horny layer). The *stratum corneum* is the outermost layer of skin and primarily is responsible for the barrier function. The epidermis is thick on the palms and soles and thin on other parts of the body, with some variations. For example, palms and soles contain sweat glands but lack sebaceous glands, which are found almost everywhere else in the skin, with the highest concentration on the face and trunk areas. Sebaceous glands and small hair follicles together form pilosebaceous units, which originate in the dermis and have follicular ducts extending through the epidermis to the skin surface. Sebaceous glands produce sebum, a lipid-like substance.[1] (Increased production by sebaceous glands is partially responsible for acne.[2])

Skin cells are called keratinocytes. They produce keratin, a protein network that gives epithelial cells resilience to mechanical stress. Keratinocytes begin at the *stratum basale* as box-shaped basal cells. As the cells mature, they migrate toward the skin surface, elongating and flattening as they divide and differentiate, ending as corneocytes in the *stratum corneum.* Corneocytes are flattened keratinocytes containing keratin tonofibrils (filaments composed of keratin and keratohyalin granules). They are often termed *dead* since they do not contain nuclei and are not capable of mitosis. Each cell covers a much larger surface area as a corneocyte compared with its basal origin. Overlapping corneocytes provide for the skin barrier.[1] (Note that abnormal keratinocyte activity accounts for some skin diseases. For example, psoriasis is associated with increased keratinocyte cell turnover, and acne is partially caused by increased keratin production.[2])

Melanocytes are pigment-producing cells in the *stratum basale.* They produce melanin, a yellow–brown/black pigment. Melanin granules are spread out into a protective layer in the *stratum corneum*, reducing UV penetration into the skin. UV radiation causes human skin to increase both melanin production and keratinocyte proliferation as a protective effort.[1]

The skin surface is normally covered with a hydrolipid film composed of sweat, oils (sebaceous lipids and free fatty acids), corneocytes, protein decomposition products, and transepidermal water. Some of these are natural moisturizing factors that help the skin retain water. Thus, the hydrolipid film is a permeability barrier that keeps the skin supple.[1]

Due to the presence of lactic acid and various amino acids from sweat, free fatty acids from sebum, and amino acids from shedding corneocytes, our skin is normally acidic, generally with a pH of 5.5 to 6. Bacteria thrive in an alkaline environment. As a result, our skin also functions as a protective acid mantle against invasion by pathogenic bacteria and fungi.[1]

The dermis, which is derived from mesoderm, is a much thicker layer that contains nerve endings and blood vessels. It is made up of collagen and elastin, which provides support for various skin structures and appendages. Eccrine (sweat) glands, hair follicles, sebaceous glands, and arrector pili muscles originate in the dermis. Subcutaneous tissue (adipose tissue with nerves and blood vessels) lies beneath the dermis.[1]

Skin is also involved in regulating body temperature, preventing dehydration, acting as a sense organ, and playing a role in vitamin D production and absorption.

AGE-RELATED CHANGES AND OTHER SKIN-RELATED CONSIDERATIONS

2 Age-related changes in the structure and functions of the epidermis and dermis are important.

In general, pediatric skin contains more water and is thinner, allowing for enhanced topical drug absorption in both the rate and amount of drug absorbed. This increases the potential for drug toxicities. Increased topical absorption and toxicity has been reported with the use of rubbing alcohol, boric acid powders, and hexachlorophene emulsions and soaps in infants and young children. Even drugs that are not normally used topically may be systemically absorbed. For example, a theophylline gel (17 mg spread over an area 2 cm in diameter) applied to the abdomen of premature infants produced therapeutic serum theophylline concentrations.[3]

Well-hydrated, unbroken skin provides maximal protection against microbial invaders. Aged skin tends to be drier, thinner, and more friable, which increases susceptibility to external insults. In addition, the healing time after skin injury may be prolonged in aged skin. For a video presentation of skin changes due to aging, see *http://www.eucerin.com/en/skin-expertise/journey-through-the-skin.*

UV radiation is associated with accelerated skin aging and skin cancers (e.g., malignant melanoma, basal cell carcinoma). Skin should be constantly protected from UV damage by the use of sunscreens that block both UVA and UVB, with a sun protection factor (SPF) of at least 15, preferably 30 or higher. Sunscreens should be applied 20 minutes before sun exposure and reapplied after sweating or swimming.

It should not be surprising that skin health is related to overall health. Exercise and adequate sleep along with maintaining a healthy, well-balanced diet are key factors. Ample daily fluid intake and regular use of moisturizers are important for skin hydration. Malnourishment can cause a patient to become immunocompromised, which may adversely affect the ability of the skin to act as a barrier. Nutritional deficiencies can cause skin problems including dry skin. Specific food allergies can cause skin reactions (e.g., rashes, hives). Patients with atopic dermatitis often have multiple food sensitivities and allergies resulting in hives and skin rashes, and/or systemic manifestations. For skin cleansing, soapless cleansers may be preferable to soap since they may cause less skin irritation. Repeated and frequent exposure to soap or other cleansers that cause cumulative irritation (e.g., with surfactants and emulsifiers) can result in irritant contact dermatitis.

PATIENT ASSESSMENT

When patients present with dermatologic disorders, a standard approach to assessment should be used. This is especially important for pharmacists who must decide whether to recommend nonprescription therapies or refer patients to medical practitioners, and to nurse practitioners and physician assistants, who must evaluate symptoms and decide whether a supervising physician or dermatologist should be involved.

PATIENT HISTORY: QUESTIONS TO ASK

3 With all skin conditions, including possible drug-induced reactions, a comprehensive patient history is important. These include questioning and physically assessing the patient to obtain the following information:

- Signs and symptoms
  - *Onset.* When did the lesions first appear? It is important to distinguish between an acute versus a chronic condition.

- *Progression*. Are the lesions improving or worsening/spreading? If lesions are worsening, how quickly are the lesions becoming more severe or widespread?
- *Timeframe*. Did the occurrence of skin lesions correlate temporally with the use of any medications? This may help to distinguish between a drug-induced condition versus a disease-related condition.
- *Location(s) and description of the lesions*. Specific details about where the lesions occur and what they look like will help to identify the type of skin condition. For example, plaque psoriasis is usually diagnosed in this manner and not through laboratory means. However, for conditions such as skin cancers,[4] a skin biopsy may be needed to establish a definitive histopathologic diagnosis.
- *Presenting symptoms*. Is there pruritus? Are the lesions painful? Pruritus is a common symptom for various skin conditions (e.g., atopic dermatitis, allergic and irritant contact dermatitis, psoriasis, bullous pemphigoid, lichen planus, pityriasis rosea) as well as systemic conditions (e.g., chronic renal failure, hepatobiliary diseases, malignancy, parasitosis) and drug reactions.[5]
- *Previous occurrence*. Has the patient presented with similar lesions before? If so, that may be extremely helpful in establishing a diagnosis and deciding on a course of treatment.

- Urgency
  - *Severity, area, and extent of skin involvement*. If a large area of the body is involved, or if signs of severe disease such as skin sloughing or hives (and in some cases if the face is involved) are present, more urgent treatment may be required; and an immediate referral to a physician would be appropriate if the patient were first seen by another health professional such as a pharmacist. In some cases a dermatology consult or an emergency hospital admission would be needed.
  - *Signs of a systemic/generalized reaction or disease condition.* Is there a fever? If there is any indication that the patient has a systemic disease condition, whether drug-induced or disease-related, and particularly if the patient is febrile, this generally indicates a more urgent situation requiring immediate medical attention. For example, erythrodermic psoriasis is distinguishable from plaque psoriasis and would require immediate referral to a physician. (See Chap. 107 for details about psoriasis.)
- Medication history
  - Is the patient using any medication that could potentially cause the observed skin condition? Temporal correlation with medication use is important in evaluating for a potential drug-induced skin reaction. Although possible, drug-induced skin reactions do not generally begin after the offending agent has already been discontinued. However, it is possible for the patient to have used the offending drug for months to years before a skin reaction occurs.
  - If the patient had presented with similar skin lesions previously, was the patient on the same or similar medication(s) at that time? If so, did the skin lesions improve after drug discontinuation?
- Differential diagnosis
  - What other possible diseases or conditions might present in this manner? Is this a disease-related problem, a drug-induced problem, or a food allergy? It is not possible to provide a thorough discussion about differential diagnoses of skin lesions in this chapter. The reader should be aware that there are differential diagnoses for each type of skin lesion. For example, besides drugs (e.g., antimalarials, cyclophosphamide, clofazimine, busulfan), other causes of hyperpigmentation include Wilson disease, malabsorption syndromes, lymphomas, porphyria cutanea tarda, physical trauma, and others.[6] Besides drugs (e.g., aspirin, nonsteroidal antiinflammatory drugs [NSAIDs], penicillins, sulfonamides, opiates), other causes of urticaria include infection (viral, bacterial, fungal, parasitic), insect stings, foods and food additives, cold, pressure, dermatographism, cholinergic stimulation (exercise, hot shower, emotional stress), hereditary C1 inhibitor deficiency, and others.[7]

LESION ASSESSMENT

As discussed briefly in the following section, the appearance of skin lesions can give some clues as to their causes. Lesions may be categorized as macules (Fig 105–1*A* and *B*), papules (Fig 105–2*A*, *B*, and *C*), nodules (Fig 105–3*A*, *B*, and *C*), blisters (Fig 105–4*A*, *B*, and *C*), or plaque and lichenification (Fig 105–5*A*, *B*, and *C*).

However, some skin conditions may cause more than one type of lesion. For example, patients with acne vulgaris may present with macules, papules, nodules, or a combination of these. Another example is psoriasis—the most common type is plaque psoriasis noted by discrete, well-defined plaques; however, there are other types of psoriasis such as guttate or erythrodermic with varying lesions. Wheals developing as a result of a drug reaction may present as papules or plaques. In contrast, some skin conditions present with a characteristic lesion. For example, lichenification is a thickening of the skin usually caused by chronic rubbing or scratching and can be seen in patients with chronic pruritus or atopic dermatitis.

Drug-Induced Skin Reactions

4 Drug-induced skin reactions can be irritant or allergic in origin.

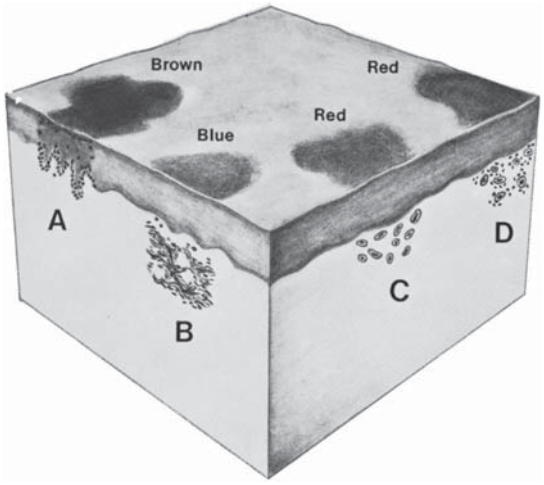
Irritant reactions are localized. Examples include chemical vaginitis, such as those resulting from vaginal douches, spermicides, and imidazoles; and vesication, produced by drug extravasation, as with agents such as anthracyclines.

Allergic reactions depend on inducing an immune response from the host; thus, the reaction may be systemic rather than limited to skin manifestations.

5 Allergic drug reactions can be classified as exanthematous, urticarial, blistering, and pustular eruptions (Fig. 105–6).[8] Skin reactions accompanied by fever are generally more serious systemic disorders. These may be life threatening in some cases, although afebrile skin reactions are not always minor (e.g., urticaria, angioedema).

Maculopapular skin reaction is an afebrile exanthematous eruption that is considered the most commonly encountered allergic skin reaction. Signs and symptoms of a maculopapular skin rash include erythematous macules and papules that may be pruritic. There is no fever, blisters, or pustules. The lesions usually begin within 7–10 days after starting the offending medication, and generally resolve within 7–14 days after drug discontinuation. However, in a previously sensitized patient the onset may be earlier (within 2–3 days). The lesions may spread and become confluent. Usual drug culprits include penicillins, cephalosporins, sulfonamides, and some anticonvulsant medications.

Drug Hypersensitivity Syndrome is an exanthematous eruption accompanied by fever, lymphadenopathy, and multiorgan involvement (including kidneys, liver, lung, bone marrow, heart, and brain). Signs and symptoms begin 1–4 weeks after starting



A.

B.

FIGURE 105-1. Macules are circumscribed, flat lesions of any shape or size that differ from surrounding skin because of their color. A. Macules may be the result of hyperpigmentation (*a*), hypopigmentation, dermal pigmentation (*b*), vascular abnormalities, capillary dilation (erythema) (*c*), or purpura (*d*). B. The clinical appearance of a drug reaction that has produced an eruption consisting of multiple, well-defined red macules of varying size that blanch upon pressure (diascopy) and are thus a result of inflammatory vasodilation. (*Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, NY:McGraw-Hill, 2003:18.*)

the offending drug, and the reaction may be fatal if not promptly treated.

This condition is also known as drug reaction with eosinophilia and systemic symptoms. It is commonly referred to by the acronym DRESS.

Usual drug culprits include allopurinol, sulfonamides, some anticonvulsants (barbiturates, phenytoin, carbamazepine, lamotrigine), and dapsone. For patients taking allopurinol, several factors increase the risk of serious skin reactions: renal impairment, hypertension, and use of thiazide diuretics or excessive allopurinol doses (i.e., not dose-adjusted for renal impairment).[9,10]

Urticaria and angioedema are simple eruptions that are caused by drugs in about 5% to 10% of cases. Other causes include foods (likely the most significant offenders) and physical factors such as cold or pressure, infections, and exposure to latex. The condition may also be idiopathic.

Urticaria has been called the cutaneous manifestation of anaphylaxis. It is an IgE-related (Type 1) allergic reaction that may be the first symptom of an emerging anaphylactic reaction. It is characterized by hives, extremely pruritic red raised wheals, angioedema, and mucous membrane swelling that typically occurs within minutes to hours (anaphylactoid) (Fig. 105–7). Individual lesions typically last less than 24 hours, but new lesions may continually develop. Offending drugs include penicillins and related antibiotics, aspirin, sulfonamides, X-ray contrast media, opiates, and others. Latex allergy is linked to the natural rubber latex (NRL) proteins, which bind with human IgE and result in contact urticaria, asthma, and anaphylaxis.[11] Aside from latex gloves and medical products, other sources of NRL proteins include rubber insoles of shoes, balloons, inflatable mattresses, and poinsettia plants.

Serum sickness-like reactions are complex urticarial eruptions presenting with fever, rash (usually urticarial), and arthralgias, usually within 1–3 weeks after starting the offending drug. This is not a true serum sickness and there is no immune complex formation, vasculitis, or renal lesions.[8]

Fixed drug eruptions are simple eruptions presenting as pruritic, red, raised lesions that may blister. Symptoms can include burning or stinging. Lesions may evolve into plaques.[8] These so called "fixed" drug eruptions recur in the same area each time the offending drug is given. Lesions appear within minutes to days and also disappear within days, leaving hyperpigmented skin for months (Fig. 105–8). Usual drug culprits include tetracyclines, barbiturates, sulfonamides, codeine, phenolphthalein, acetaminophen, and NSAIDs.

Stevens-Johnson syndrome (SJS) and *toxic epidermal necrolysis* (TEN) are complex blistering eruptions that, together with erythema multiforme (EM), are known as acute bullous disorders. They are histologically similar and have been considered part of an "EM spectrum of diseases."[12] EM may be considered a dermatologic disorder not associated with a drug reaction, whereas SJS and TEN are immune complex or cell-mediated allergic responses to offending agents, including drugs.[12] Because of their histologic similarity, SJS and TEN have been considered either distinct disorders or progressions of the same disorder based on the percentage of skin area involved, and these two entities are often discussed together.[12]

SJS/TEN are rare, severe, and life-threatening conditions with an acute onset (within 7–14 days of drug exposure). Patients present with generalized tender/painful bullous formation with accompanying systemic signs and symptoms, including fever, headache, and respiratory symptoms, that rapidly deteriorate. Lesions show rapid confluence and spread, resulting in extensive epidermal detachment and sloughing.[12] This may result in marked loss of fluids, drop in blood pressure, electrolyte imbalances, and secondary infections, including *Staphylococcus epidermidis* and methicillin-resistant *Staphylococcus aureus* (*MRSA*). Usual drug culprits include sulfonamides, penicillins, some anticonvulsants (hydantoins, carbamazepine, barbiturates, lamotrigine), NSAIDs, and allopurinol.

Acneiform drug reactions are simple pustular eruptions caused by medications that induce acne (whiteheads or blackheads). The onset is usually about one to three weeks. Common drug culprits include corticosteroids, androgenic hormones, some anticonvulsants, isoniazid, and lithium. Topical acne treatments can be used to manage symptoms if the offending drug cannot be discontinued or replaced.

Acute generalized exanthematous pustulosis (AGEP) is a complex pustular eruption characterized by acute onset (within days after starting the offending drug), fever, diffuse erythema, and many pustules. About one half of patients have other cutaneous lesions, and one quarter have mucosal erosions. Generalized desquamation occurs two weeks later.[8] Usual drug culprits include beta-lactam antibiotics, macrolides, and calcium channel blockers.

FIGURE 105-2. Papules are small, solid, elevated lesions that are usually less than 1 cm in diameter. The major portion of a papule projects above the plane of the surrounding skin. *A*. Papules may result, for example, from metabolic deposits in the dermis (*a*), from localized dermal cellular infiltrates (*b*), and from localized hyperplasia of cellular elements in the dermis and epidermis (*c*). Papules with scaling are referred to as papulosquamous lesions, as in psoriasis (see Chap. 107). *B*. Clinical examples of papules. The examples are two well-defined and dome-shaped papules of firm consistency and brownish color, which are dermal melanocytic nevi. *C*. Multiple, well-defined, and coalescing papules of varying size are seen. Their violaceous color, glistening surface, and flat tops are characteristic of lichen planus. (*Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, NY: McGraw-Hill, 2003:18.*)

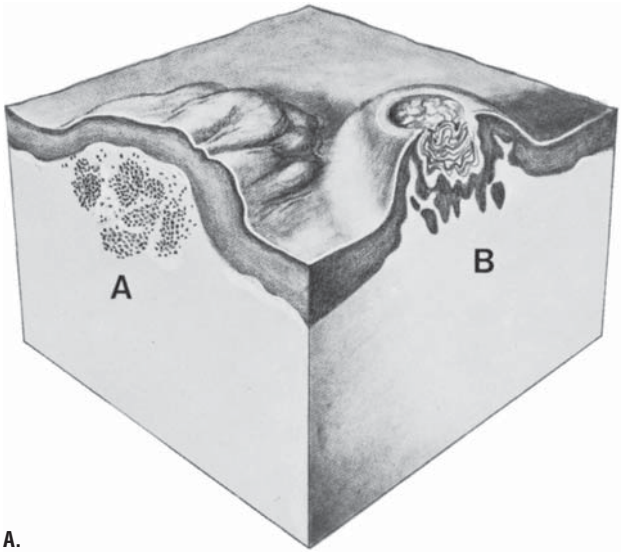
Other Drug-Induced Skin Reactions *Hyperpigmentation* of the skin (Fig. 105–8) may be related to increased melanin (e.g., hydantoins), direct deposition (e.g., silver, mercury, tetracyclines, antimalarials), or other mechanisms (some cytotoxic drugs, such as 5-fluorouracil, may cause banding on nails or tracking along veins).

Photosensitivity reactions (Fig. 105–9) may be phototoxic or photoallergic. Drugs that induce phototoxic reactions absorb ultraviolet A (UVA) light, resulting in skin damage. Severity tends to be proportional to the drug dose. Usual drug culprits include amiodarone, tetracyclines, sulfonamides, psoralens, and coal tar.

Drug-induced photoallergic reactions result from UVA transformation of medications into allergens. In this syndrome, skin damage may occasionally spread beyond sun-exposed skin. These reactions require sensitization to the offending drug and are not dose-related. Usual drug culprits include sulfonamides, sulfonylureas, thiazides, NSAIDs, chloroquine, and carbamazepine.

Management and Prevention of a Drug-Induced Skin Reaction 6 The first rule of thumb in managing skin reactions is to remember that not all are drug-induced. In clinical practice, a diagnosis of drug-induced skin reaction is often a diagnosis of exclusion (i.e., the diagnosis is reached after other possible diagnoses have been ruled out). Potential foods and other causes have to be thoroughly investigated, and a detailed patient interview is important, as discussed earlier. Consistent with the assessment for any adverse drug reaction, the likelihood of a drug-induced skin reaction should be categorized as probable, possible, or not probable (unlikely). It may not be possible to categorize a drug-induced skin reaction as definite, as this requires rechallenge with the potentially offending agent, and this should not be done with most reactions. Reactions are often unpredictable adverse drug reactions unrelated to the normal pharmacologic effects of the drug. Fortunately, unpredictable adverse drug reactions (e.g. allergic, idiosyncratic, carcinogenic) usually affect only a small percentage of patients.

If a drug-induced skin reaction is suspected, the most important treatment in nearly all cases is discontinuing the suspected drug as quickly as possible and avoiding the use of potential cross-sensitizers. In most instances, that is the only specific treatment required. In severe cases a short course of systemic corticosteroids may be needed. In a few instances it may be possible to continue the offending drug and "treat through" the reaction[8] (e.g., ampicillin-associated maculopapular skin rash).



A.

C.

B.

FIGURE 105-3. Nodules are palpable, solid, round or ellipsoidal lesions. Depth of involvement and/or substantive palpability, rather than diameter, differentiates a nodule from a papule. *A*. Nodules may extend into the dermis or subcutaneous tissue (*a*) or be located in the epidermis (*b*). *B*. This photograph shows a well-defined, firm nodule with a smooth and glistening surface through which telangiectasia (dilated capillaries) can be seen; there is central crusting indicating tissue breakdown and thus incipient ulceration (nodular basal cell carcinoma). *C*. Multiple nodules of varying size can be seen (melanoma metastases). (*Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, NY: McGraw-Hill, 2003:18.*)

The next step is to control symptoms associated with the drug reaction (e.g., pruritus). Furthermore, any signs or symptoms of a systemic or generalized reaction may require additional supportive therapies specific to the severity and type of signs and symptoms seen. For high fevers, an antipyretic such as acetaminophen is more appropriate than aspirin or an NSAID, as these may exacerbate skin lesions for some reactions. Depending on the type of skin reaction, the affected skin condition may take days to weeks or months to resolve.

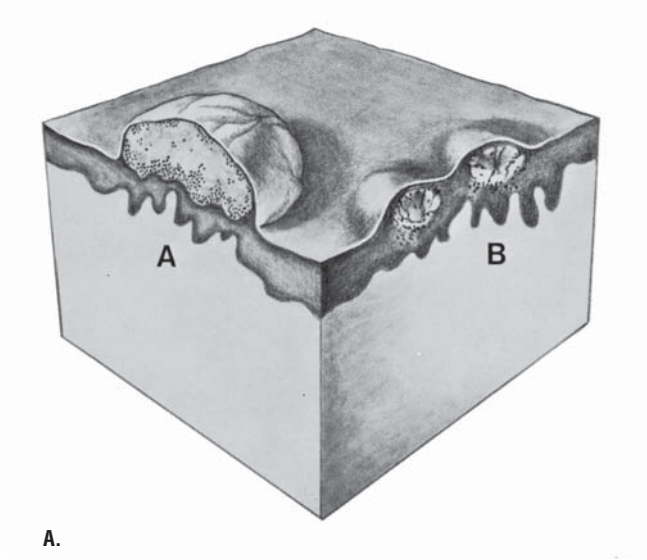
For patients with life-threatening SJS/TEN, supportive measures such as maintenance of adequate blood pressure, fluid and electrolyte balance, use of broad-spectrum antibiotics and vancomycin for secondary infections, and intravenous immunoglobulin (IVIG) may all be appropriate. IVIG has been shown to halt disease progression and enhance recovery for SJS/TEN.[12] The use of corticosteroids for SJS/TEN is somewhat controversial; although they may curb disease progression they may also increase the risk of infection and thus contribute to increased mortality.[12] If used, relatively high initial doses followed by rapid tapering as soon as disease progression halts is indicated.[12] Refer to the Drug-Induced Skin Reactions case in the *Pharmacotherapy Casebook* to further explore management.

Patient education should be provided. Advice to the patient should include information about the suspected drug and potential drugs to avoid in the future, and which drugs may be used. Potential cross-sensitizers should be identified. For patients with photosensitivity reactions, provide information about preventive measures such as the use of sunscreens and sun avoidance (Fig. 105–9). For patients with severe reactions (e.g., anaphylaxis), information about MedicAlert programs may be appropriate. Genetic predisposition has not been established for most drug-induced reactions, but for severe reactions such as SJS/TEN or hypersensitivity syndromes, the risk may be higher in first-degree relatives of affected patients.

COMMON SKIN DISORDERS

Contact Dermatitis

7 Contact dermatitis is defined as an inflammation of the skin caused by irritants or allergic sensitizers.[13] It describes and includes all skin reactions resulting from direct contact of the skin or mucous membranes with an exogenous agent, which may be a "foreign" molecule such as a drug or chemical, UV light, or temperature.[13]



A.

B.

FIGURES 105-4. Vesicles and bullae are the technical terms for blisters. Vesicles are circumscribed lesions that contain fluids, while bullae are vesicles that are larger than 0.5 cm in diameter. *A.* Subcorneal vesicles (*a*) result from fluid accumulation just below the stratum corneum, whereas spongiotic vesicles (*b*) result from intercellular edema. *B.* Multiple translucent subcorneal vesicles are extremely fragile, collapse easily, and thus lead to crusting (arrows). These lesions are staphylococcal impetigo. (*Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:18.*)

The skin or mucous membranes may react nonimmunologically and/or immunologically to an exogenous agent, resulting in either an irritant or allergic skin reaction as described earlier. However, the distinction between an allergic contact dermatitis (ACD) and irritant contact dermatitis (ICD) has become increasingly blurred[13]; ICD is often a diagnosis of exclusion, as in cases where patch test results for ACD are negative.[13]

In addition, an exogenous dermatitis can be superimposed on an endogenous skin eruption such as acne.[13] Irritant effects may be considerably enhanced by occlusion. Contact dermatitis must also be distinguished from atopic dermatitis and other dermatologic conditions such as dyshidrotic dermatitis, Lichen simplex dermatitis, acne rosacea, and other conditions. (See Chap. 108 for a discussion on atopic dermatitis).

Contact dermatitis is a common skin problem for which 5.7 million physician visits are made per year.[13] Almost any of the more than 85,000 chemicals in the world environment may be a skin irritant, and more than 3,700 substances have been identified as contact allergens.[13] Although all age groups may be affected, ACD is rare in the first years of life (<10 years), but the rate of occurrence in older children may exceed that in adults.[13]

The prevalences of ACD to individual allergens is similar in children and adults; allergens include nickel, fragrances, *Toxicodendron* (formerly known as *Rhus*), and rubber chemicals.[13] There may be a slight female preponderance, presumably due to exposure to specific contactants in jewelry and cosmetics.[13]

The clinical presentation of contact dermatitis is that of an eczematous inflammation, with erythema, vesicles, papules, crusting, fissuring, or scaling (see Figs. 105–10 and 105–11*A* and *B*). The area may itch, burn, or sting and may be extremely pruritic. The severity may range from a mild, short-lived condition to a severe and persistent condition but is rarely life-threatening.[13] The gross and histologic appearances of ICD and ACD are often similar and may be difficult to distinguish.[13] However, the rash/lesion for ICD is frequently localized whereas for ACD it may extend beyond the borders of the exposed area of contact, and the reaction may rarely become systemic (e.g., latex allergy).

ICD is generally a multifactorial response involving contact with a substance that chemically abrades, irritates, or otherwise damages the skin; cellular damage in ICD occurs via T-cells (activated by irritant or innate mechanisms) releasing proinflammatory cytokines.[13] ACD is the clinical manifestation of contact hypersensitivity;[14] skin allergens tend to be low-molecular weight molecules (haptens) that become immunogenic after conjugation with skin proteins, resulting in a complex series of interactions that involve antigen-presenting Langerhans and/or other dendritic cells, or CD4+ and CD8+ T cells,[13] including IL-17–producing T_H17 cells.[14]

Since ACD is immunologically-mediated the patient may have tolerated exposure to the offending agent for some time, making it more difficult to pinpoint the culprit. Furthermore, the reaction may continue to develop for some time after the offending agent is removed.

8 The first goal of therapy in the management of contact dermatitis involves identifying, withdrawal, and avoidance of the offending agent. A thorough history including work history must be carefully reviewed for potential contactants. Nonwork activities such as hobbies (e.g., painting, gardening, camping, fishing) may be additional potential sources of exposure. Patch testing is the gold standard for identifying a contact allergen[13] but it is impractical to test an unlimited number of allergens.

Standard panels of allergens have been designed and validated by collaborative research dermatologic societies; however, these may account for only 25% to 30% of the most relevant contact allergens.[13] Many patients need additional testing, Customized patch tests may be needed, depending on the patient's exposure history.[13]

The most common causes of occupational contact dermatitis are chromium (leather exposure), rubber and rubber additives (gloves), nickel (work tools and metal working), food ingredients including intact proteins (for food processing workers), fertilizers and pesticides (for farmers), and handwashing (disinfectants, irritants in soaps).[13]

The most common cause of plant dermatitis is *Toxicodendron (Rhus)* dermatitis. This genus includes poison ivy, poison oak, and poison sumac. These plants contain the offender urushiol oil, one of several oleoresins that are sensitizers and irritants. Urushiol oil is also found in mango skin, cashew nut oil, ginkgo (female) leaves, Japanese lacquer, and Indian marking ink.[13]

FIGURE 105-5. *A*. Plaque is a mesa-like elevation that occupies a relatively large surface area relative to its height above the skin surface. *B*. Well-defined, reddish, scaling plaques can coalesce to cover large areas of the back and buttocks, with some regression in the center as is common in psoriasis (see Chap. 107). *C*. Lichenification, a thickening of the skin and accentuation of skin, can result from repeated rubbing. It develops frequently in patients with atopy, and also occurs in eczematous dermatitis or other conditions associated with pruritus. Lesions of lichenification are not as well defined as most plaques and often show signs of scratching, such as in excoriations and crusts. (*Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. FIGURE 105-6. Types of cutaneous drug eruptions. Adapted from Knowles S. Drug-induced Skin Reactions, Figure 46–1. In: Patient Self-Care (PSC). Ontario, Canada: Canadian Pharmacists Association, 2002.[8]

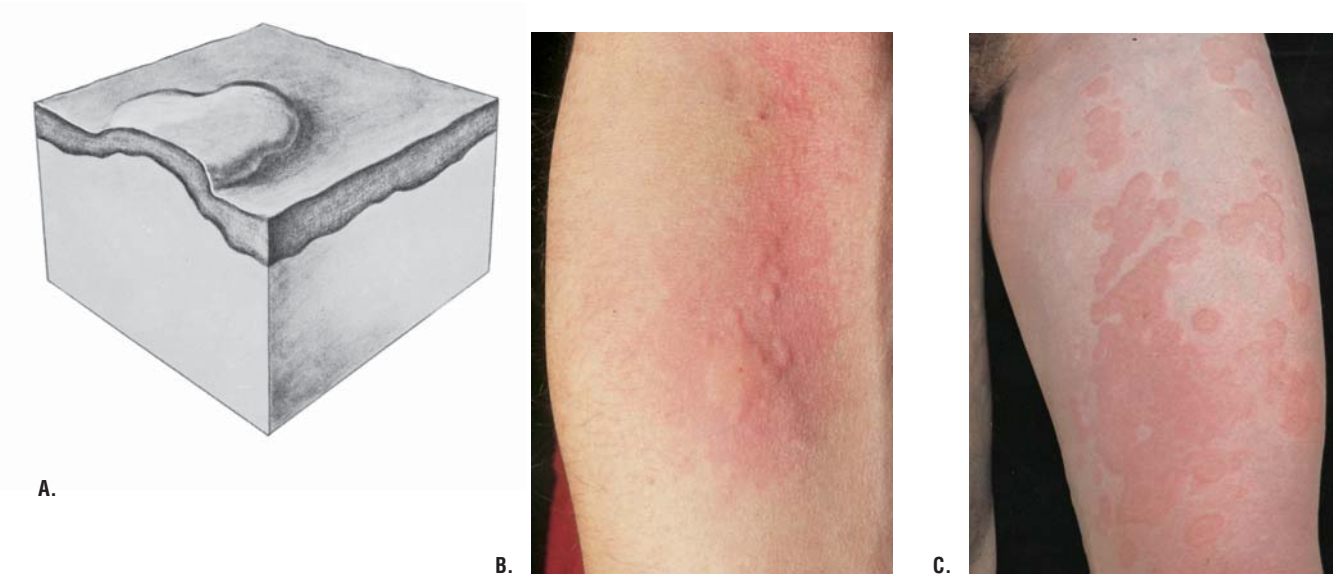

FIGURE 105-7. *A*. Wheals are rounded or flat-topped papules or plaques that are characteristically evanescent, disappearing within hours. An eruption consisting of wheals is termed urticaria and usually itches. *B*. Wheals may be tiny papules 3 to 4 mm in diameter, as in cholinergic urticaria. *C*. Alternatively, wheals may present as large, coalescing plaques, as in allergic reactions to penicillin, other drug, or alimentary allergens. (*Reprinted with permission from Stewart MI, Bernhard JD, Cropley TG, Fitzpatrick TB. The structure of skin lesions and fundamentals of diagnosis. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:18.*)

Cosmetics and personal hygiene products, such as hair conditioners and shampoos, nail polishes and hardeners, mascara, foundations, antiperspirants and deodorants, and toothpastes, may all contain potential causes of contact dermatitis. The most important classes are fragrances, preservatives, formulation excipients, glues, and sunblocks;[13] fragrances are among the most common causes of contact dermatitis in the United States.[13]

9 The second goal of therapy in contact dermatitis is to provide symptomatic relief while decreasing skin lesions. The affected skin may require supportive treatment such as the use of cold compresses to sooth and cleanse the skin, or topical corticosteroids to help resolve the inflammatory process. Compresses are applied to wet or oozing lesions, removed, remoistened, and reapplied every few minutes for a 20–30 minute period. Calamine lotion or Burow solution (aluminum acetate) may be soothing.

Topical corticosteroids are considered the mainstay of treatment, and ACD responds better than ICD. Generally, higher potency corticosteroids are used initially, switching to medium or lower potency corticosteroids as the condition improves.[13] Refer to the

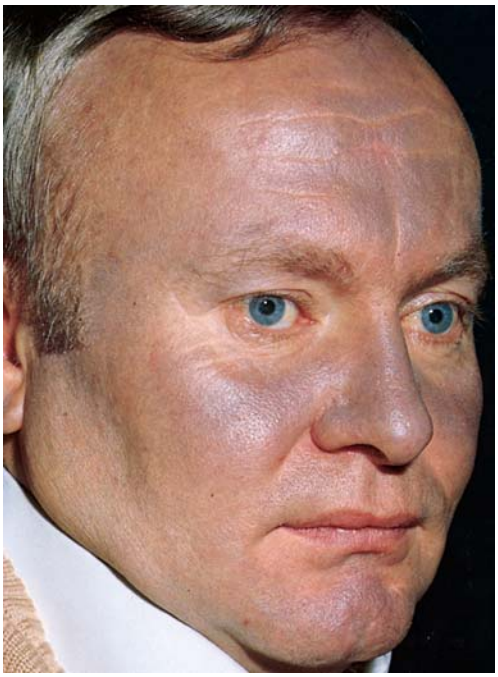

FIGURE 105-8. Hyperpigmentation. This patient exhibits a striking amiodarone-induced, slate-gray pigmentation of the face. The blue color (ceruloderma) is caused by deposition of a brown pigment in the dermis, contained in macrophages, and endothelial cells. *(Reprinted with permission from Ortonne J-P, Bahadoran P, Fitzpatrick TB, et al. Hypomelanoses and hypermelanoses. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:876.)*

The severe vesiculobullous reaction is typical for urushiol, an oily poisonous irritant found in Toxicodendron spp. (*Reprinted with permission from Belsito DV. Allergic contact dermatitis. In: Freedberg IM et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:1167.*)

Topical Corticosteroid Potency Chart in Chap. 107 (Table 107–2) for specific examples.

Other treatments may be effective. Tacrolimus ointment has been shown to be effective for nickel-induced ACD in a small randomized placebo-controlled clinical trial.[15] Oatmeal baths or oral first-generation antihistamines may provide relief for excessive itching. If the affected areas are already dry or hardened (e.g., lichenification), wet dressings applied as soaks (without removal for up to 20–30 minutes) will soften and hydrate the skin (these should not be used for acute exudating lesions, as the skin area may become macerated, further damaging its barrier function).

The third goal of contact dermatitis therapy is to implement preventive measures. Prevention involves both primary and secondary measures.

Primary prevention may be done in the workplace, by initiating surveillance programs and educating workers about proper skin care and chemical exposure.

Secondary prevention involves the use of moisturizers to prevent dryness and fissuring of the skin. The efficacy of barrier creams is controversial.[13] The damaged skin may need to be protected against secondary infections, at least until the acute stage subsides. Debris, produced by oozing, scaling, or crusting, should not be allowed to accumulate. Rarely, some workers may have persistent dermatitis despite removal of offenders, and a small number of workers change jobs because of severe recalcitrant OCD.[13]

A final goal of therapy is to provide patient and caregiver information and support, helping them to develop coping strategies for contact dermatitis, as required.

Diaper Dermatitis

⑩ Diaper dermatitis, more commonly known as diaper rash, is most often seen in infants, although the condition may also be seen in older adults who wear diapers for incontinence. It is an acute inflammatory dermatitis affecting the buttocks, genital, and perineum regions that are covered by the diaper. The rash is erythematous, and severe rashes may have vesicles or oozing erosions. The rash may be infected by *Candida* species and present with confluent red plaques, papules, and pustules.

Management of diaper dermatitis includes frequent diaper changes, air drying (removing the diaper as long as practical), gentle cleansing (preferably with nonsoap cleansers and lukewarm water), and the use of barriers. Commercial diaper wipes containing fragrance or alcohol should be avoided. Zinc oxide has astringent and absorbent properties, and provides an effective barrier. Petrolatum also provides a water-impermeable barrier but has no absorbent ability and may trap moisture.

A.

B.

FIGURE 105-11A AND 105-11B. 105–11*A* This patient has allergic chronic dermatitis involving the dorsal aspects of the hands and the distal forearms, but with minimal involvement of the palms. In this case, contact dermatitis is secondary to use of thiuram present in rubber gloves, prescribed for treatment of an irritant hand dermatitis. 105–11*B*. This patient, a florist, has allergic contact dermatitis as a consequence of exposure to tuliposide A, the allergen in Peruvian lilies (Alstroemeria spp.). Note the more prominent involvement of the palms of the dominant hand. (*Reprinted with permission from Belsito DV. Allergic contact dermatitis. In: Freedberg IM et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:1167.*)

Patients with candidal (yeast) diaper rash should be treated with a topical antifungal agent then covered by a barrier product. Imidazoles are the treatment of choice for this type of diaper rash. Once the rash subsides, the antifungal agent should be stopped and the barrier product continued.

In severe inflammatory diaper rashes a very low potency topical corticosteroid (hydrocortisone 0.5% to 1%) may be used for short periods of one to two weeks.

Skin Cancers

Actinic keratoses are precursors to the development of skin cancers. UV radiation (with UVA a greater risk than UVB) may induce abnormal keratinocyte changes. These present as actinic keratoses. These lesions can develop into squamous cell or basal cell carcinomas.

Actinic keratoses are most often found in elderly fair-skinned patients and on chronically sun-exposed areas, such as hands, forearms, head, and neck.

Squamous Cell Carcinoma (SCC) is a skin cancer most commonly seen in older patients (Fig. 105–12). Risk factors include fair complexion, prolonged sun exposure, UV radiation (including PUVA used for treatment of psoriasis), long-term immunosuppression (including the use of biologic response modifiers for treatment of conditions such as psoriasis). Most SCCs present as firm, flesh-colored, or erythematous papules or plaques. Treatment is primarily via surgical excision.

Basal Cell Carcinoma (BCC) is a very common skin disorder (Fig. 105–13). BCC most commonly presents as a pigmented nodule on the head and neck. Treatment may vary based on histology and may involve surgical excision as well as the use of topical agents such as imiquimod or antineoplastic agents, such as 5-fluorouracil.

Malignant melanoma, unless detected early and excised, often produces systemic metastases. Its incidence has increased over the past few decades, with an estimated 1 in 65 Americans developing melanoma during their lifetimes.[16]

FIGURE 105-12. Squamous Cell Carcinoma. This case of squamous cell carcinoma must be differentiated in diagnosis from chondrodermatitis nodularis helicis, which, unlike the carcinoma, is painful. (*Reprinted with permission from Grossman D, Leffell DJ. Squamous cell carcinoma. In: Freedberg IM, Eisen AZ, Wolff K, et al., eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York: McGraw-Hill, 2003:738.*)

FIGURE 105-13A AND 105-13B. Basal Cell Carcinoma. 105-13*A*. Basal cell carcinoma, nodular type. 105-13*B*. An ulcerated nodular basal cell carcinoma. New York: McGraw-Hill, 2003:749.*)

A changing mole is often a harbinger of melanoma. These are detected by skin examination; dermatologists often have melanoma clinics for this purpose. Moles are examined for asymmetry, irregular borders, variegated colors, and size. (See Fig. 105–14*A* and *B*). Full-body skin exams are important in screening for melanoma, as it can occur anywhere on the skin.[16]

Other risk factors include prolonged sun exposure and ability to tan, family history, and drug treatments such as PUVA or biologic response modifiers used for psoriasis.

Suspicious pigmented lesions should be fully excised as soon as possible rather than biopsied; malignant melanomas are best diagnosed and microstaged with an excisional biopsy of the entire lesion.[17] Delayed diagnosis of malignant melanoma directly affects patient survival adversely.[16] Treatment may also include systemic antineoplastic therapy, such as temozolomide or dacarbazine for metastatic melanoma.

CONCLUSIONS

This chapter provided coverage about the skin and associated age-related changes, lesion assessment and recognition, drug-induced skin reactions, contact dermatitis, diaper dermatitis, and briefly discussed common skin cancers. Other common skin disorders

CHAPTER 106

Acne Vulgaris

DEBRA SIBBALD

KEY CONCEPTS

1. Acne is a highly prevalent disorder affecting many adolescents and adults.
2. It is an extremely complex disease with an etiology originating from multiple causative and contributory factors.
3. Elements of pathogenesis involve defects in epidermal keratinization, androgen secretion, sebaceous function, bacterial growth, inflammation, and immunity.
4. Acne vulgaris cannot be "cured." Goals of treatment of this chronic disorder include control and alleviation of symptoms by reducing the number and severity of lesions, slowing progression, and limiting disease duration and recurrence. Key elements for patient adherence to therapy include prevention of long-term disfigurement associated with scarring and hyperpigmentation and avoidance of psychologic suffering.
5. The most critical target for treatment is the microcomedone, as the entire pathogenic cascade of acne is arrested if follicular occlusion is minimized or reversed. This involves a combination of treatment measures, integrating pharmacologic protocols targeting all four mechanisms involved in acne pathogenesis: increased follicular keratinization, increased sebum production, bacterial lipolysis of sebum triglycerides to free fatty acids, and inflammation.
6. Nondrug measures are aimed at both long-term prevention and treatment. Patients should eliminate aggravating factors, maintain a balanced, low-glycemic load diet, and control stress. They should wash twice daily with a mild soap or soapless cleanser, and restrict cosmetic use to oil-free products. Comedone extraction results in immediate cosmetic improvement in about 10% of patients. Shaving should be done as lightly and infrequently as possible, using a sharp blade or electric razor.
7. First-, second-, and third-line therapies should be selected and altered as appropriate for the severity and staging of the clinical presentation.
8. Treatment is directed at controlling the disorder, not curing it. Regimens should be tapered over time, adjusting to response. The smallest number of agents should be used at the lowest possible dosages to ensure efficacy, safety, avoidance of resistance, and patient adherence.
9. Once control is achieved, simplify the regimen but continue with some suppressive therapy. It takes 8 weeks for a microcomedone to mature; thus, any therapy must be continued beyond this duration to assess efficacy in terms of comedonal and inflammatory lesion count, control or progression of severity, and management of associated anxiety or depression. Safety endpoints include monitoring for adverse effects of treatment.
10. Through empathic and informative counseling, the health professional can motivate the patient to continue long-term therapy.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

In this chapter, we review the latest developments in understanding acne vulgaris and its treatment. The contents provide an analysis of the physiology of the pilosebaceous unit; the epidemiology, etiology and pathophysiology of acne; relevant treatment with nondrug measures; and comparisons of pharmacologic agents, including drugs of choice recommended in best-practice guidelines. Options include a variety of alternatives such as retinoids, antimicrobial agents, hormones, and light therapy. Formulation principles are discussed in relation to drug delivery. Patient assessment, general approaches to individualized therapy plans, and monitoring evaluation strategies are presented.

EPIDEMIOLOGY

1 Acne vulgaris is a chronic disease and the most common one treated by dermatologists. The lifetime prevalence of acne approaches 90%, with the highest incidence in adolescents. Prevalence data available from the European Union, United States, Australia, and New Zealand shows that acne affects 80% of individuals between puberty and 30 years of age.[1] Other studies have reported acne in 28% to 61% of school children aged 10–12 years; 79% to 95% of those 16–18 years of age; and even in children aged 4–7 years.[2–4]

The onset of acne vulgaris during puberty occurs at a younger chronologic age in girls than boys. Most patients continue to have symptoms into their mid-20s, and there is evidence that the duration of acne may last into middle age for most women, recorded in 54% of women and 40% of men older than 25 years of age.[5] In puberty, acne is often more severe in boys in about 15% of cases, which is tenfold greater than in girls. Women often have more severe forms during adulthood. When untreated, acne usually lasts for several years until it spontaneously remits.

There are believed to be no gender differences in acne prevalence, although such differences are often reported and may represent social biases. In urban clinics, there is a clear preponderance of girls seeking treatment. There is also a perception that acne is less prevalent in rural populations. This is supported by the data from Varanasi where 21.35% of boys (13–18 years) from rural areas had acne versus 37.5% of those from the urban areas.[6]

An international group of epidemiologists, community medicine specialists, and anthropologists have questioned whether acne might be predominantly a disease of Western civilization.[7] They assert that since acne vulgaris is nearly universal in westernized societies (afflicting 79% to 95% of the adolescent population), one causative factor might be the Western glycemic diet. While this hypothesis is based on the observation that primitive societies subsisting on traditional (low glycemic) diets have no acne, the theory awaits validation and acceptance by the dermatologic community.

ETIOLOGY

2 Acne is a multifactorial disease. Genetic, racial, hormonal, dietary, and environmental factors have been implicated in its development. Its psychologic impact can be severe.

Four major etiologic factors are involved in the development of acne: increased sebum production, due to hormonal influences; hyperproliferation of ductal epidermis; bacterial colonization of the duct with *Propionibacterium acnes;* and production of inflammation in acne sites. These are reviewed in the Pathophysiology section later in this chapter.

The role of heredity in acne has not been clearly defined; however, there is a significant tendency toward more serious involvement if one or both parents had severe acne during their youth.

Environmental factors play a major role in determining the severity and extent of acne and may influence the choice of topical treatments. Heat and humidity may induce comedones; pressure or friction caused by protective devices such as helmets, shoulder pads, or pillows, and excessive scrubbing or washing can exacerbate existing acne by causing microcomedones to rupture. Hair styles that are low on the forehead or neck may cause excessive sweating and occlusion, exacerbating acne. In most cases acne is worse in winter and improves during the summer, suggesting a salutary effect of sunlight. However, in some cases exposure to sunlight worsens the disease.[8]

The importance of psychologic factors in this prolonged and capricious condition has been repeatedly stressed. Emotions such as intense anger and stress can exacerbate acne, causing flares or increasing mechanical manipulation. This is probably the result of increased glucocorticoid secretion by the adrenal glands, which appears to potentiate the effects of androgens.[9]

Dietary influences are the focus of current investigations. In the past, acne was not felt to be influenced by diet, but patients could restrict certain foods they perceive exacerbate acne (chocolate, cola drinks, milk and milk products).[10,11] These recommendations, which still persist in some guidelines, are based on one or two poorly designed studies conducted more than 40 years ago. They have largely been discounted by well-designed current studies. A discussion of the issues surrounding dietary influences is elaborated as a Current Controversy later in this chapter.

PATHOPHYSIOLOGY

3 The pathogenesis of acne progresses through the following four major stages:

1. Increased follicular keratinization
2. Increased sebum production
3. Bacterial lipolysis of sebum triglycerides to free fatty acids
4. Inflammation

Acne usually begins in the prepubertal period, when the adrenal glands mature, and progresses as androgen production and sebaceous gland activity increase with gonad development.

As shown in Figure 106–1, acne results from the development of an obstructed sebaceous follicle, called a *microcomedone*. Sebaceous glands increase their size and activity in response to circulating androgens. Most patients with acne do not overproduce androgens (with some exceptions); instead, they have sebaceous glands that are hyperresponsive to androgens.[12] The composition of sebum is changed, with a reduction in linoleic acid. The growth of keratinocytes changes. The infrainfundibulum increases its keratinization of cells with hypercornification and development of the microcomedone, the primary lesion of both noninflammatory and inflammatory acne.[13] Cells adhere to each other in an expanding mass, which forms a dense keratinous plug. In particular androgens, hormones could be a stimulus to pilosebaceous duct hypercornification. Sebum, produced in increasing amounts by the active gland, becomes trapped behind the keratin plug and solidifies, contributing to open or closed comedone formation.

The pooling of sebum in the follicle provides ideal substrate conditions for proliferation of the anaerobic bacterium *Propionibacterium acnes*, generating a T cell response, which results in inflammation.[13] *P. acnes* produces a lipase that hydrolyzes sebum triglycerides into free fatty acids. These free fatty acids may trigger the changes that lead to an increase in keratinization and microcomedone formation.[14,15] This closed comedone, or whitehead, is the first clinically visible lesion of acne. It takes approximately 5 months to develop. The closed comedone is almost completely obstructed to drainage and has a tendency to rupture.[16–18]

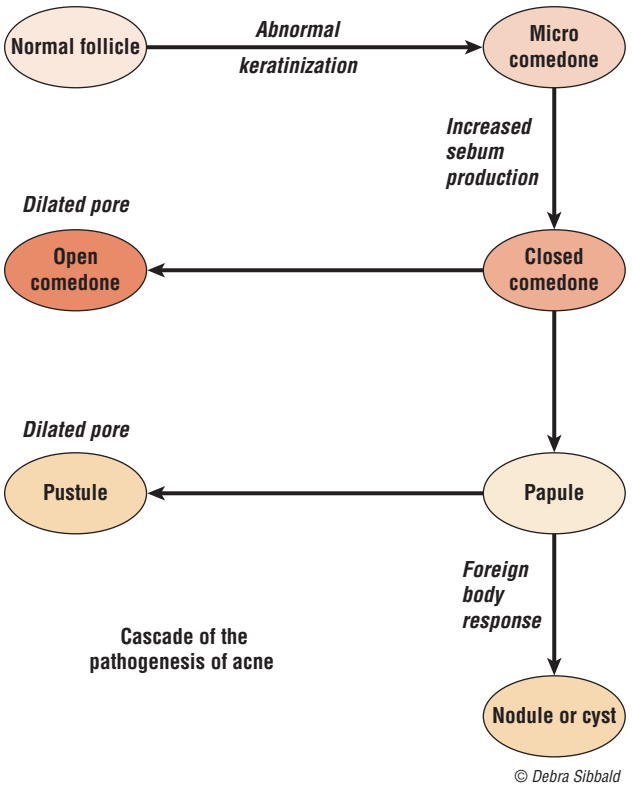

FIGURE 106-1. Cascade of the Pathogenesis of Acne

As the plug extends to the upper canal and dilates its opening, an open comedone, or blackhead, is formed. Its dark color is not due to dirt but to either oxidized lipid and melanin or to the impacted mass of horny cells. The cylindrically shaped, open comedone is very stable and may persist for a long time as soluble substances and liquid sebum escape more easily. Acne that is characterized by open and closed comedones is termed *noninflammatory acne*.

Both recruitment of polymorphs into the follicle during the inflammatory process and release of *P. acnes*-generated chemokines lead to pus formation. The pus eventually bursts on the surface with resolution of the inflammation or into the dermis. *P. acnes* also produces enzymes which increase the permeability of the follicular wall, causing it to rupture, releasing keratin, hair, and lipids and irritating free fatty acids into the dermis. Several different types of inflammatory lesions may form, including pustules, nodules, and cysts and may lead to scarring.

Hyperpigmentation and scarring are two sequelae of acne. A time delay of up to 3 years between acne onset and adequate treatment correlates to degree of scarring and emphasizes the need for early therapy.[10,11]

ACNE VULGARIS CAN BE NONINFLAMMATORY OR INFLAMMATORY.

- Noninflammatory acne is characterized by open and closed comedones.
  - The closed comedo is visible as a 1 to 2 mm whitehead most easily seen when the skin is stretched.
    - Is the first clinical sign of acne
    - Has a tendency to rupture
  - The open comedo, or blackhead, is larger, approximately 2 to 5 mm and is dark-topped with contents extruding
    - Is relatively stable
- Inflammatory acne is traditionally characterized as having papulopustular and/or nodular lesions
  - A pustule is formed from a superficial aggregation of neutrophils
    - Appears as a raised white lesion filled with pus, usually less than 5 mm in diameter
    - Superficial pustules usually resolve within a few days without scarring
  - A nodule is produced through deeper, dermal, inflammatory infiltration.
    - Is the most severe variant of acne
    - Appears as warm, tender, firm lesions, with a diameter of 5 mm or greater
    - May be suppurative or hemorrhagic within the dermis, may involve adjacent follicles and sometimes extend down to fat
  - Cysts are suppurative nodules named because they resemble inflamed epidermal cysts.
    - Cystic acne may show double comedones, resulting from prior inflammation and fistulous links between neighboring sebaceous units.
- Progression of inflammatory lesions:
  - Pustules and cysts often rupture spontaneously and drain a purulent or bloody but odorless discharge.[19]
  - Inflammatory lesions may itch as they erupt and can be tender or painful.
  - Often resolution of these lesions leaves erythematous or pigmented macules that can persist for months or longer, especially in dark-skinned individuals.
  - Nodules and deep lesions may result in scarring.
- Acne lesions can occur anywhere on the body apart from the palms and soles.
  - Are usually located on the face, back, neck, shoulders, and chest
  - May extend to buttocks or extremities
  - One or more anatomic areas may be involved in any given patient
  - The pattern of involvement, once present, tends to remain constant.
- Skin, scalp, and hair are frequently oily.

CLINICAL PRESENTATION AND DIAGNOSTIC CONSIDERATIONS

To correctly diagnose acne vulgaris, the clinician considers patient assessment which includes distinguishing all the presenting signs and symptoms of the clinical presentation (see box), as well as considering a differential diagnosis and the possibility of drug-induced acne.

PATIENT ASSESSMENT

Patient assessment begins with establishing a therapeutic relationship with the patient, in which their understanding, expectations, concerns, and behaviors are considered. All relevant information must be elicited from the patient to determine if their drug-related needs are being met and to identify drug therapy problems. Rational drug therapy decisions and a plan for delivering patient goals, along with follow-up evaluation, are made.

CONDUCTING A PATIENT ASSESSMENT

When acne is the chief complaint, the clinician begins by eliciting all details of presenting signs and symptoms.

Determine Signs and Symptoms

Palliating factors (e.g., sunlight) and provoking factors (e.g., premenstrual flares, humid environments, excessive sweating; exposure to chemicals; occlusive clothing; friction; oily cosmetics; manual manipulation; stress) should be determined.

Next, the quality and quantity of lesions should be considered (comedonal or inflammatory).

Then, determine the regions of involvement (e.g., face, back, chest) and areas of radiation (e.g., localized, generalized, symmetric or nonsymmetric).

To assess severity grading, several taxonomies are used but none are accepted universally. The following system includes factors such as lesion type, location of lesions, and number and status of irreversible sequelae:[20,21]

Type 1: Comedones only, fewer than 10 lesions on the face, no lesions on the trunk, and no scarring

Type 2: Papules, 10–25 lesions on the face and trunk, mild scarring

Type 3: Pustules, more than 25 lesions, moderate scarring

Type 4: Nodules or cysts, extensive scarring

Inflammatory acne can also be graded using a mild, moderate, and severe hierarchy that addresses the kind of inflammatory lesion. Severity grading under this scheme is as follows:

Mild: few to several papules or pustules and no nodules

Moderate: several to many papules or pustules and few to several nodules

Severe: numerous and/or extensive papules or pustules and many nodules[22]

In addition to determining severity, the patient should be asked about associated symptoms (e.g., itch, pain, fever). Finally, the time of onset of lesions and time patterns (e.g., intermittent, constant, progressive) must be established.

Medical Conditions

Once the full picture of signs and symptoms is clarified, ascertain if the patient has medical conditions which either contribute to or coexist with acne and confuse the clinical presentation, if endocrine factors are significant in the patient (e.g. irregular menses, hirsutism, alopecia), and if the patient is pregnant or atopic.

Medication History

A full medication history should be established. Determine if the patient is taking or using a product that could cause or interact with acne signs and symptoms, based on literature evidence. Has the patient tried any nondrug measures, and what was the effect on acne signs and symptoms? Has the patient used any product successfully or unsuccessfully to treat acne lesions recently or during past episodes? Has a health care practitioner or another individual (friend, relative, media) made a treatment recommendation for the acne signs and symptoms? If so, was this attempted and what was the result?

Allergies

Determine if specific allergies affect drug therapy. Could an allergy be causing the acne symptoms, or could an allergy present a contraindication to acne therapy? Social habits, such as diet, smoking, or alcohol use, should be discussed.

Family History

Family history should be elicited. Is there a genetic predisposition to acne? If so, determine the nature of the acne presentation in these individuals.

Psychosocial Issues

Are there significant psychosocial issues affecting control of acne? Have global and disease specific quality of life (QOL) indicators or health-state utilities been assessed? QOL indicators represent patients' perceptions and reactions to their health. Assessing QOL impairment in patients with acne may aid in management by evaluating psychologic impacts, which may not correlate with clinical severity; aid in detection of depression or need for psychologic care; and improve therapeutic outcomes.

Examples of global scales that have been used to evaluate acne include Skindex[23] and Dermatology QOL Index;[24] examples of acne specific scales include the Acne-specific QOL questionnaire[25] and the Acne QOL Scale.[26] Health-state utilities (such as time trade-off [TTO]) are quantitative measures of patient preferences of health outcomes ranging from 0 (death) to 1 (perfect health) and can be used in clinical trials as outcome measures of treatment effects. TTO utilities for acne in the range of 0.94 to 0.96 can be compared with those of other diseases (e.g., 0.92 for epilepsy, 0.94 for myopia), and help to identify the impact of acne on self-perception and psychologic functioning.[27]

DIFFERENTIAL DIAGNOSIS

Acne vulgaris is rarely misdiagnosed. The conditions most commonly mistaken for acne vulgaris include rosacea, perioral dermatitis, gram-negative folliculitis, and drug-induced acne.[28]

Acne rosacea (adult acne) is a chronic relapsing condition, occurring after age 30 in fair-complexioned persons and involving blood vessels. The first sign is easy flushing followed by development of inflammatory lesions, with edema, papules, and pustules appearing on the nose, cheeks, chin, and forehead, and telangiectasia (spider veins) developing as the condition progresses. The affected area may be sensitive to the touch.

Rosacea differs from acne vulgaris in several ways. Its onset is not linked to increased androgens or endocrine changes; comedones are not usually present; aggravating factors are different and include ingestion of alcohol, spicy foods, or hot drinks (especially those containing caffeine); smoking; overexposure to sunlight; and exposure to temperature extremes, friction, irritating cosmetics, and steroids. Rosacea is not curable, progressively worsens, and may ultimately result in rhinophyma (enlarged nose). Refer patients to a physician for treatment, as antibiotics, particularly topical metronidazole, may be required.[29]

Perioral dermatitis occurs primarily in young women and adolescents and is characterized by erythema, scaling, and papulopustular lesions commonly clustered around the nasolabial folds, mouth, and chin. The cause is unknown.[29]

Gram-negative folliculitis *(Proteus, Pseudomonas, Klebsiella)* may complicate acne, with a sudden change to pustules or large inflammatory cysts occurring after long-term treatment of acne with oral antibiotics. Folliculitis may be caused by staphylococci. There is a sudden onset of superficial pustules around the nose, chin, and cheeks. Patients with suspected folliculitis should be referred to a physician.[29]

Several conditions include acne vulgaris as a characteristic component, and understanding the mechanisms involved in these syndromes provides insight into the pathogenesis of acne. These include polycystic ovary syndrome (elevated androgen levels); PAPA syndrome (pyogenic arthritis, pyoderma gangrenosum, acne; early onset arthritis with increased inflammatory activity), and SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, osteitis syndrome; sterile inflammatory arthro-osteitis, with *P. acnes* as a possible trigger).[13]

DRUG-INDUCED ACNE

In addition to the conditions induced by drugs that were presented in Chap. 105, acneiform eruptions can also be caused by medications. Systemic corticosteroids can cause a pustular inflammatory form of acne, especially on the trunk. Onset is abrupt at 2 to 6 weeks after initiation of therapy. Acne has also been associated with most of the potent topical steroids, but not with hydrocortisone, which lacks the ability to inhibit protein synthesis. Discontinuation of the steroid results in an initial worsening of appearance due to removal of the antiinflammatory action of the steroid itself. Caution patients about this reaction, which can be subdued through judicious use of topical hydrocortisone.[30–32]

Antiepileptics and tuberculostatics are the most commonly implicated in drug-induced acne, followed by lithium. Other heavy metals inducing acne include cobalt in vitamin B_{12}.[33] Halogens, especially an excess of iodide in seafood, salt, and health foods, can exacerbate acne.

In addition, certain minor ingredients in cosmetics have been implicated in cosmetic acne, including isopropyl myristate, cocoa butter, and fatty acids.

TREATMENT

The first step in determining a safe and efficacious treatment regimen for acne vulgaris is to establish desired outcomes for the patient, regarding both short- and long-term goals.

DESIRED OUTCOME (GOALS OF TREATMENT)

4 Acne vulgaris requires long-term control, as it cannot be cured. This basic principle needs to be stressed with the patient to establish motivation to adhere to lengthy treatment regimens, which involve both addressing current symptoms and signs and taking preventive measures. Basic goals of treatment include alleviation of symptoms by reducing the number and severity of lesions, slowing the progression of signs and symptoms, limiting the disease duration and recurrence, prevention of long-term disfigurement associated with scarring and hyperpigmentation, and avoidance of psychologic suffering.

GENERAL APPROACH TO TREATMENT

5 The most critical target for treatment is the microcomedone, because by eliminating the follicular occlusion the whole cascade of acne is arrested. This will involve a combination of preventive measures to reduce or eliminate risk and aggravating factors and treatment measures. These should integrate nondrug and pharmacologic protocols aimed at cleansing as well as targeting all four mechanisms involved in acne pathogenesis. First-line, second-line, and third-line therapies should be selected and altered as appropriate for the severity and staging of the clinical presentation. Treatment is directed at controlling the disorder, not curing it. Regimens should be tapered over time, adjusting to response. The smallest number of agents should be used at the lowest possible dosages to ensure efficacy, safety, avoidance of resistance, and patient adherence. Once control is achieved, simplify the regimen but continue with some suppressive therapy. It takes 8 weeks for a microcomedone to mature, thus any therapy must be continued beyond this duration in order to assess efficacy.[32]

NONPHARMACOLOGIC THERAPY

6 Encourage patients with acne to discontinue or avoid any aggravating factors, maintain a balanced, low-glycemic-load diet and control stress. Evidence shows that by being empathic and informative during counseling, the health professional may motivate the patient to continue long-term therapy.[8,9,28] One of the first approaches to nondrug management of acne is attention to cleansing techniques. Shaving recommendations, comedone extraction, dietary considerations, issues relating to ultraviolet light, and prevention of cosmetic acne should be reviewed with patients.

Cleansing

Cleansers often contain surfactant systems to remove fat from the skin surface. The oil is dispersed from the skin into the surfactant system; however, the active ingredient is sometimes trapped and removed upon rinsing, Also, the balance between cleanliness and drying or irritation should be taken into account. Most patients prefer products with foaming action, and these must contain additional secondary surfactants to enhance the foam and condition the skin.

Soaps are the most widely used cleansing products, but do not lend themselves to efficient delivery of active drug. Two main disadvantages exist. As soaps are rinsed off, the deposit of active agent will be small; and the high pH required in soaps may degrade some active ingredients and be less tolerable on sensitive skin. Soapless cleansers are an alternatives to soaps.[34]

Patients should wash no more than twice daily with a mild, nonfragranced opaque or glycerin soap or a soapless cleanser. Acne patients often wash too frequently, attempting to remove surface oils. There is no evidence indicating that this is helpful, as surface lipids do not affect acne.[35] Contributory lipids are deep in the follicle and are not removed through washing. Antiseptic cleansers, while producing a clean, refreshed feeling, remove only surface dirt, oil, and aerobic bacteria. They do not affect *P. acnes*. There is no evidence that any particular washing regimen is superior. Scrubbing should be minimized to prevent follicular rupture. Soaps produce a drying effect on the skin due to detergent action. As medicated cleansers require increased contact time, this drying action is pronounced, especially with peeling agents. Avoid cream-based cleansers.

Polyester cleansing sponges (e.g., Buf-Puf) are synthetics that abrade the skin surface, removing superficial debris. They are unlikely to unseat comedones, considering the structure of these lesions. The sponges are available in soft or coarse textures, with or without soap. Caution patients against using a circular or rubbing motion that will increase irritation, and instruct them to use single, gentle, continuous strokes on each side of the face, from the midline out toward the ears.

Cationic-bond strips that become activated by water are available. The dirt and oil in the pores is anionic. As the strip dries, the cationic-bond binds the anionic dirt and removes it when the strip is peeled off.

Shaving

Males should try both electric and safety razors to determine which is more comfortable for shaving. When using a safety razor, the beard should be softened with soap and warm water or shaving gel. Shaving should be done as lightly and infrequently as possible, using a sharp blade and being careful to avoid nicking lesions. Strokes should be in the direction of hair growth, shaving each area only once.

Comedone Extraction

Comedone extraction is useful and painless and results in immediate cosmetic improvement although it has not been widely tested in clinical trials. Pretreatment with a peeler for 4 to 6 weeks often facilitates the procedure.[32] Following cleansing with hot water, a comedone extractor is placed over the lesion and gentle pressure applied until the contents are expressed. This removes unsightly lesions, preventing progression to inflammation. A correctly sized extractor allows the central keratin plug to extrude through the opening. The small end of a plastic eye dropper, with bulb removed, may also be used. These instruments should be cleaned with alcohol after each use. Some initial reddening may be apparent. If the contents are not expressed with modest pressure, patients should not continue since improper extraction may further irritate the skin. A physician should be consulted if this technique is too difficult for the patient to manage. Since the follicle is difficult to remove completely, comedones may recur between 25 and 50 days following expression. Fewer than 10% of comedone extractions are a complete success, but the process is useful when done properly.[19]

Comedo removal may be helpful in the management of comedones resistant to other therapies, but it has not been well studied despite long-standing clinical use. Also, while the procedure cannot affect the clinical course of the disease, it can improve the patient's appearance, which may positively affect adherence with the treatment program.

Ultraviolet Light

Although ultraviolet light was recommended in the past for desquamation, the practice is no longer advisable because of the well-established carcinogenic and photoaging effects of ultraviolet exposure. Moreover, inflamed skin is more susceptible to the damaging effects of ultraviolet light. Patients taking tretinoin may show heightened sensitivity.[36]

Before exposure to sunlight, patients with acne should apply sunscreens (SPF 15) in alcohol or oil-free bases and avoid using the acnegenic benzophenones. Sunscreen should be applied as the first product.

CLINICAL CONTROVERSY: LIGHT THERAPY

Recently some authors proposed "diverse" light therapies (using various wavelengths) as a new acne treatment. The outcomes of existing trials are contradictory. Light therapies for acne are believed to work by killing *P. acnes* and by damaging and shrinking sebaceous glands, reducing sebum output. Studies report few adverse effects,[117] and any adverse effects are temporary. [119] Light therapies may be given once or twice weekly as a course of 6 to 10 treatments, with each irradiation lasting 10 to 20 minutes.[119] Treatment is not available universally; it is accessed privately via dermatologists or clinics, and can be expensive. *P. acnes* produce endogenous porphyrins that absorb light to form highly reactive singlet oxygen, which destroys the bacteria.[119] Since porphyrins have peak absorption at blue light wavelengths, blue light is often used to treat acne. Red light is also absorbed by porphyrins and can penetrate deeper into the skin,[120] where it may directly affect inflammatory mediators. Other light therapies attempt to selectively target and damage sebaceous glands directly, reducing their size and thus sebum output.[121] These include infrared lasers, low-energy pulsed dye lasers, and radiofrequency devices.[119]

Photodynamic therapy (PDT) uses specific light-activating creams, which are absorbed into the skin and amplify the response to light therapy but tend to produce more severe adverse effects. There are concerns that PDT may interfere with the skin's natural immune mechanisms [122] and cause long-term skin damage.

An increase in transforming growth factor (TGF)-β1 mRNA 24 hours after treatment with lasers has been observed. TGF-β1, an immunosuppressive cytokine, stimulates the formation of collagen. Its increase following laser treatment may promote resolution of inflammation.[123]

Light therapies are increasingly popular among consumers. Medical science is needed to establish whether light of different wavelengths is effective.[119] A Cochrane review protocol will investigate the current state of evidence for use of light therapy in acne.[124]

Prevention of Cosmetic Acne

Persistent low-grade acne in women after their mid-20s is frequently caused by heavy cosmetic use. Adolescent acne in younger women may be exacerbated with makeup overuse. The problem is perpetuated when the resultant blemishes are concealed with more cosmetics.

Advise patients to stop using oil-containing cosmetics and avoid cosmetic programs that advocate applying multiple layers of cream-based cleansers and cover-ups. These are advertised through the media and often available through Internet shopping with promotional bonuses. Three-step basic systems usually combine medicated and nonmedicated ingredients, although it may not be apparent by their cosmetic names that therapeutic agents are included. They often start with cleansers, in lotions or creams, which may contain a multitude of unnecessary ingredients, including medicated peelers, oils, fragrances, and preservatives. Often drugs are included in subtherapeutic or low doses, including salicylic acid, sulfur, or benzoyl peroxide. The second step is generally a "toner" or "refresher" which is usually water- or alcohol-based and might contain medicated ingredients such as alpha-hydroxy acids (e.g., glycolic acid), which are mild comedolytic agents, or even glycerin as a humectant. The final product, often called intensive or repairing solutions, usually contains the lowest strength of peelers such as benzoyl peroxide, sulfur, or salicylic acid; plus potentially sensitizing fragrances and preservatives; or oil-soluble sunscreens that are not identified on the label. Bases may have significant oil content. There may be additional products to supplement as necessary to the base routine of 3 steps, such as masks or spot treatments. Multiple-step cosmetic programs are often costly, and should be avoided in favor of simple cleansers and more effective single-ingredient peelers at optimal concentrations.

The term *noncomedogenic* may refer to either water-based vehicles or products that are free of substances known to induce comedones. They are not necessarily oil-free. Water-based cosmetics may contain significant amounts of oil in the form of undiluted vegetable oils, lanolin, fatty acid esters (butyl stearate, isopropyl myristate), fatty acids (stearic acid), fatty acid alcohols, cocoa butter, coconut oil, red veterinary petrolatum, and sunscreens containing benzophenones. Water-based products are more likely to contribute to pore blockage than oil-free products.

Oil-free makeups are well-tolerated and lipstick, eye shadow, eyeliner, eyebrow pencils, and loose face powders are relatively innocuous. Heavier, oil-based preparations, particularly moisturizers and hairsprays, clog pores and accelerate comedone formation.[37]

The patient should restrict cosmetic use to products labeled oil-free rather than water-based, including makeup, moisturizers, or sunscreens. Coverup cosmetics for acne are available in several skin tones and in lotion and cream forms. They often contain peeling agents, antibacterial agents, or hydroquinone. Most contain sulfur. They may be applied as cosmetics 2 or 3 times daily, over the entire face or to individual lesions. However, since the spread time of oil-free makeup is decreased, best results are achieved if applied to one-quarter of the face at a time. Topical medication should be applied after gentle cleansing and a foundation lotion may be used sparingly as a concealer.[38,39,40]

Since the action of most therapeutic acne agents is to dry the skin, the use of moisturizers is counterproductive. Active agents such as alpha-hydroxy acids (glycolic, lactic, pyruvic, and citric acids) may be present in the cosmetic formulation, since they reduce corneocyte adhesion.[41] Patients with acne should be restricted to oil-free alpha-hydroxy acid products unless absolutely necessary because of treatment with strong drying agents or isotretinoin.

Vehicles

The formulation of an acne vehicle must consider the technical characteristics of maintaining and delivering the drug in an active state together with the need for an elegant product that the patient will enjoy using, so that it is more likely to be applied as required and deliver the full benefit. Physically and chemically, the vehicle will be used with one or more of the following goals: reduce excess oil, control bacteria associated with acne, reduce the effects of hyperkeratinization, and unclog pores. Performance, safety, and stability should be maximized while addressing technical and commercial factors.

Immiscible liquids might be delivered in oil-in-water or water-in-oil emulsions. In addition to having undesirable oil content, these vehicles also contain humectants, thickeners, preservatives, and fragrance, all of which may be problematic.

Solutions are simpler formulations, and there is a trend to use them as the soaking liquid for wipe products made with fibrous cloths. The viability of these kinds of products must take into consideration whether packages are resealable if they contain multiple wipes, and whether the volatility of the solvent will affect storage and availability of the active agent or cause crystallization. Solutions are used mainly with topical antibiotics, which are often dissolved in specific types of alcohol. While some antibiotics are only soluble in ethyl alcohol, isopropyl alcohol is generally better able to remove oil from the skin surface and is preferred for nonmedicated vehicles. An 8% glycolic acid solution is available for use alone or for incorporation in topical antibiotic preparations. Solutions and washes can be more easily applied to large areas such as the back.[42]

Nongreasy solutions, gels, lotions and creams should be selected as bases for topical acne preparations. Gels are very useful as they are totally oil-free along with mixtures of water or alcohol. Lotions and creams will contain some oil-phase ingredients. Discourage moisturizers and oil-based products. Lotions are slightly less drying than gels, and creams are more emollient. Many gels contain ethanol or isopropyl alcohol. Propylene glycol is sometimes present in small amounts to add viscosity and lessen the drying effects of strong peeling agents. Gels are drying but may cause a burning irritation in some patients and may prevent certain kinds of cosmetics from adhering to the skin.[43] Propylene glycol gels are easy to apply and dry without a visible or sticky film. Nonalcoholic gels may be as effective and less drying than alcoholic solutions. Alcoholic or acetone gels are usually more drying and provide better penetration of the active ingredient.

Consider the patient's skin type and preferences in the choice of vehicle for topical agents. Patients with oily skin often prefer vehicles with higher proportions of alcohol (solutions and gels), while those with dry or sensitive skin prefer nonirritating lotions and creams. Lotions can be used with any skin type and can be easily spread over hair-bearing skin, but will cause burning or dryness if they contain propylene glycol. Compatibility of vehicles and agents with cosmetics should also be considered.

How to Use Topical Preparations

Topical preparations should not be applied to individual lesions but to the whole area affected by acne to prevent new lesions from developing, using care around the eyelid, mouth, and neck to avoid chafing. Lotions should be applied with a cotton swab once or twice a day after washing or at bedtime if they leave a visible residue.

Psychologic Approaches/ Hypnosis/Biofeedback

The psychologic effects of acne may be profound and the American Academy of Dermatology expert workgroup unanimously concluded that effective acne treatment can improve the emotional outlook of patients.[44] There is weak evidence of the possible benefit of biofeedback-assisted relaxation and cognitive imagery.[45,46]

Dressings

A pilot double-blind, randomized study of 20 patients has shown some benefit of treatment with a hydrocolloid acne dressing when compared with tape dressings for improving mild to moderate inflammatory acne vulgaris. Results showed greater reduction over 3 to 7 days in the overall severity of acne and inflammation, along with greater improvement in redness, oiliness, dark pigmentation, and sebum casual level. Less ultraviolet B light reachs the skin surface with the hydrocolloid dressing in place.[47]

CLINICAL CONTROVERSY

Tobacco smoking has numerous effects on the skin. Dermatologists have begun to counsel people to quit tobacco smoking as a potential auxiliary treatment for acne. Studies have examined the relationship between tobacco smoking and acne but have had inconsistent results, as follows: (1) people with acne had a decreased tobacco smoking prevalence compared with national estimates of tobacco smoking incidence,[125] (2) smokers were reported to have an increase in acne prevalence,[126,127] and (3) the prevalence of acne among adolescents was found not to be associated with tobacco smoking.[128,129] Differences existed in the patient populations and control groups included in these studies and might explain the incongruity in results. Patient populations differed in age range, acne severity, and demographic locations. Control groups used for comparison included national statistics for smokers, patients with skin disease other than acne attending the same clinic, and nonsmokers compared with smokers with quantified consumption.

In light of the conflicting study results concerning the association between acne and tobacco smoking in observational studies, more thorough investigation from randomized controlled trials is needed. A Cochrane review protocol will investigate the current state of evidence for the effect of smoking cessation on acne.[130]

PHARMACOLOGIC THERAPY

Successful pharmacologic therapy must address one of the four mechanisms involved in the pathogenesis of acne. There are numerous agents available that prove one or more of these actions and are therefore effective. However The choice of active pharmacologic therapy depends on severity.

Mechanisms of drug action relating to acne pathogenesis are illustrated in Figure 106–2.

Drug Treatments of First Choice

For mild to moderate acne with predominantly noninflammatory lesions (comedones), few inflammatory lesions, and no scars, active agents of first choice include those that correct the defect in keratinization by producing exfoliation most efficaciously. Such agents include topical retinoids, salicylic acid, and benzoyl peroxide. Sulfur

CLINICAL CONTROVERSY

The role of dietary influences in acne has always been controversial. Guidelines asserting little or no psychologic influences are largely based upon results of a 1969 single-blind crossover study, which had a number of methodologic flaws, showing no significant differences in lesion count or sebum characteristics following ingestion of enriched chocolate bar versus a control bar without cocoa butter and chocolate liquor. A subsequent small study also showed no differences in count or grade of acne in medical students who were asked to consume the food they thought most likely to worsen acne for 7 days.[131] It is now suggested that this information has been widely overinterpreted, resulting in an inappropriate dismissal of potential effects of dietary ingestions on acne.[132]

More recent studies have reported association between various dietary influences and presentation of acne, including an association between acne and intake of milk, perhaps due to natural hormonal components and/or other bioactive molecules in milk.[133,134] Other studies suggest that insulin-like growth factor (IGF), increased by ingestion of high glycemic loads, may play a role in acne.[135,136]

Patients who consumed a low-glycemic-load diet, compared with a conventional high-glycemic-load diet, had improvements of facial acne after 12 weeks. Accompanying changes in physical and endocrinologic parameters suggest that decreases in total energy intake, body weight, and indices of androgenicity and insulin resistance may also be associated with observed improvements in acne.[137] Further studies that examined the effect of a low-glycemic-load diet versus controls on acne and fatty acid composition of skin surface triglycerides showed increases in the ratio of saturated to monounsaturated fatty acids which correlated with acne lesion counts and increased sebum outflow. This suggests a possible role of desaturase enzymes in sebaceous lipogenesis and the clinical manifestation of acne; these require further investigation.[138] Another study that reported an improvement in acne and insulin sensitivity in low-glycemic-load diets compared with controls, suggests nutrition-related lifestyle factors play a role in the etiology of acne. Independent effects of weight loss versus dietary intervention need to be isolated.[139]

While still controversial, diet is thought to play a role in the development or progression of acne vulgaris and further studies are ongoing.

and resorcinol are weaker exfoliators. Since the comedo is the initial lesion even in inflammatory acne, these agents are used to correct the defect in keratinization in all cases of acne.

For moderate to severe acne, with predominantly inflammatory lesions (papules, pustules, few nodules) and some scars, it is important to reduce the population of *P. acnes* in the follicle and the generation of its extracellular products and inflammatory effects. Drugs of choice include benzoyl peroxide; topical antibiotics, such as clindamycin, alone or in combination with benzoyl peroxide; and oral antibiotics, such as erythromycin, tetracycline, or minocycline. Retinoids, including tretinoin, adapalene, and tazarotene, and azaleic acid are also recommended for moderate to severe acne.

For severe acne with inflammatory lesions (papules, pustules), extensive nodules and cysts, and scars, or acne resistant to other approaches, a drug that decreases sebaceous activity, such as antiandrogens, isotretinoin, or topical and oral antibiotics, should be added to the regimen.[48]

Published Guidelines

There is considerable heterogeneity in the acne literature. Various evidence-based guidelines available from multiple American, Canadian, European, Scandinavian, and South African sources do not provide concordance or clarity on all issues. Recommendations should be based on critical appraisal and interpretation of the literature combined with clinical experience.

An expert committee of the American Academy of Dermatology convened in 2007 to define guidelines for acne therapy and identify nine clinical questions to structure the primary issues in diagnosis and management (Table 106–1).[44] These guidelines address the management of adolescent and adult patients presenting with acne but not the consequences of disease, including the scarring, postinflammatory erythema, or postinflammatory hyperpigmentation. The use of light and laser therapy was not addressed in the guidelines.

General Information Regarding Efficacy and Safety

The guidelines and recommendations of the American Academy of Dermatology considered the efficacy and safety of various treatments, such as topical agents, systemic antibacterial agents, hormonal agents, isotretinoin, miscellaneous therapies, complementary and alternative therapies, and dietary restriction, based on levels of evidence and best clinical practice.[44] More specific information about the efficacy and safety of each of these specific modalities is outlined below in sections on each individual agent.

Alternative Drug Treatments

Herbal and alternative therapies have been used to treat acne. Although these products appear to be well tolerated, very limited data exist regarding their safety and efficacy.

Tea Tree Oil This contains terpinen-4-ol which appears responsible for some antimicrobial activity. One clinical trial has demonstrated that topical tea tree oil is effective for the treatment of acne, although the onset of action is slower than with other topical treatments.[49] In a study comparing 5% tea tree oil gel with 5% benzoyl peroxide lotion, both reduced the number of inflamed and noninflamed lesions. A randomized double-blind clinical trial performed in 60 patients with mild to moderate acne vulgaris reported 5% tea tree oil gel was more effective than placebo in terms of total acne lesions counting (TLC, 3.55 times) and acne severity index (ASI, 5.75 times) after a period of 45 days.[50] A systematic review of randomized clinical trials concludes there is no compelling evidence showing that tea tree oil is effective in any dermatologic condition.[51]

Tea Lotion Tea lotion is another natural plant extract that has been tested in acne vulgaris. A single-blind randomized controlled study of 60 patients compared a freshly prepared 2% tea lotion with placebo twice daily for 2 months in the treatment of acne vulgaris.[52] The authors reported significantly reduced mean lesion count of papules and pustules after 8 weeks for the tea lotion, and the difference between the 2 study groups was statistically significant.

Other Herbal Agents Topical and oral ayurvedic compounds have been reported to have value in the treatment of acne.[53,54] Notwithstanding, the use of botanical preparations, which are nonstandardized, should be discouraged in favor of traditional quality-controlled preparations that have evidence of efficacy.[55]

Glycolic Acid Another agent considered as an alternative therapy for acne vulgaris is glycolic acid. The efficacy and tolerability of a 0.1% retinaldehyde/6% glycolic acid combination (Diacneal) has been evaluated for mild to moderate acne vulgaris.[56] Physician and

[a]An expert panel of the American Academy of Dermatology developed these clinical recommendations using the best available evidence. The panel rated evidence using the Strength of Recommendation Taxonomy (SORT), which uses this three-point scale:
I. Good quality patient-oriented evidence.
II. Limited quality patient-oriented evidence.
III. Other evidence including consensus guidelines, extrapolations from bench research, opinion, or case studies.
Similarly, recommendations were ranked as follows:
A. Recommendation based on consistent and good quality patient-oriented evidence.
B. Recommendation based on inconsistent or limited quality patient-oriented evidence.
C. Recommendation based on consensus, opinion, or case studies.

patient ratings of acne symptom severity and tolerance performed at baseline and months 1, 2, and 3 showed mean numbers of papules, pustules, and comedones were significantly reduced from month 1 on, demonstrating that glycolic acid is effective and well tolerated in mild-to-moderate acne vulgaris.

Both glycolic acid–based and salicylic acid–based peeling preparations have been used in the treatment of acne. There is very little evidence from clinical trials published in peer-reviewed literature supporting the efficacy of peeling regimens.[44] Further research on the use of peeling in the treatment of acne needs to be conducted to establish best practices for this modality.

Hydroquinone To control pigmentation, hydroquinone, which reversibly damages melanocytes, has been used as a hypopigmenting agent in concentrations of 2% to 4%, in preparations of clear or tinted gels, which are more drying, and as vanishing or opaque, flesh-tinted creams, with or without alpha-hydroxy acids or sunscreens. Hydroquinone causes fading of epidermal but not dermal pigmentation. Onset of response is usually 3 to 4 weeks, and the depigmentation lasts for 2 to 6 months but is reversible. While effective in the removal of melanin, hydroquinone has been clinically found to be a possible carcinogen and causes a blue-black discoloration known as ochronosis.[57]

After considering new data and information on the safety of hydroquinone, the U.S. Food and Drug Administration (FDA) issued a proposed ruling in 2006 about hydroquinone products. The FDA proposed reversing earlier rules that hydroquinone is generally recognized as safe and effective; however, the FDA has also allowed the products to stay on the U.S. market until a final rule is issued. The FDA is also considering all prescription hydroquinone products to be new drugs requiring an approved new drug application for continued marketing.

Hydroquinone has already been banned in Japan, much of the European Union, and Africa.

Treatment of Scarring Drug and non measures for scar resolution are important in acne vulgaris since many patients are scarred despite adequate treatment. For patients with mild scarring, nonprescription alpha-hydroxy acids may be used, while severe scarring may be corrected with other treatment modalities that require consultation with a dermatologist. Dermabrasion, local excision, collagen implants, chemical peels (e.g., 70% glycolic acid)

and laser therapy have been used to improve scarring. Atrophic scars can be treated with laser resurfacing. Usually the scar is not completely removed, but a more cosmetically acceptable result is achieved. Keloids and hypertrophic scars can be treated with intralesional triamcinolone, cryotherapy, topical steroids and silicone sheeting. Surgical options for scars include excision, augmentation with collagen or fat, chemical peels, subcision, and injection of autologous fibroblasts.[58]

Special Populations

About 20% of young infants (2 to 3 months of age) develop papules, pustules, and less commonly closed or open comedones, primarily on the cheeks, due to placental transfer of maternal androgens (neonatal acne). The acne subsides within a few months with regular maturation. Boys are affected more often than girls because of a transient increase in testosterone secretion during the third and fourth month of intrauterine life. *Malassezia* spp. may be involved in pathogenesis.[19] Resolution occurs without therapy.[59] Infants with neonatal acne may have more severe teenage acne.[19]

Drug Class Information

This section reviews the pharmacology and mechanisms as related to pathophysiology for pharmacologic options recommended in the guidelines for mild, moderate, and severe acne. It will also review evidence of efficacy and safety as well as kinetics, interactions, dosing, and administration when relevant.

Exfoliants (Peeling Agents) Exfoliants induce continuous mild drying and peeling by primary irritation, damaging the superficial layers of the skin, and inciting inflammation. This stimulates mitosis, thickening the epidermis, and increasing horny cells, scaling, and erythema. A decrease in sweating results in a dry, less oily surface and may superficially resolve pustular lesions.

In the past, a rabbit model was used to study the efficacy of topical exfoliants in retarding tar-induced comedone formation and accelerating their loss (comedolysis). In this animal model, retinoic acid (tretinoin) was most active, compared with benzoyl peroxide and salicylic acid, which were respectively less active. Data from peer-reviewed literature regarding the efficacy of sulfur, resorcinol, sodium sulfacetamide, aluminum chloride, and zinc are limited. Traditional nonprescription exfoliants, including phenol, resorcinol, betanaphthol, sulfur, Vleminckx's solution, and sodium thiosulfate, are weak or ineffective. These agents are not comedolytic given that they affect the superficial epidermis rather than the hair canal. They have been supplanted by superior effective agents.[60,61]

Resorcinol. This phenol derivative is less keratolytic than salicylic acid. It is said to be both bactericidal and fungicidal. Products containing resorcinol 1% to 2% have been used for acne, often in combination with other peeling agents, such as sulfur or salicylic acid. The FDA considers resorcinol 2% and resorcinol monoacetate 3%, in combination with sulfur 3% to 8%, to be safe and effective and that the combination may enhance the activity of sulfur. However, the FDA is not convinced that resorcinol and resorcinol acetate are safe and effective when used as single ingredients, and has placed such products in Category II (not generally recognized as safe and effective, or misbranded).[61]

Resorcinol is an irritant and sensitizer and should not be applied to large areas of the skin or on broken skin. It produces a reversible, dark brown scale on some dark-skinned individuals.

Protective packaging is important as resorcinol is reactive to light and oxygen. It has good solubility in both water and alcohol and is heat stabile Thus, it is incorporated into a variety of products, including emulsions.[62]

Salicylic Acid. Salicylic acid has been used for many years for the treatment of acne, although few well-designed trials of its safety and efficacy exist. It is a natural ingredient in many plants, such as willow tree or willow bark, is a beta-hydroxy acid, and penetrates the pilosebaceous unit. It has comedolytic activity, although the concentrations in commercial preparations (less than 2% to 3%) are generally low. While concentrations less than 2% may actually increase keratinization, concentrations between 3% and 6% are keratolytic, softening the horny layer and producing shedding of scales. Its mechanism remains unresolved, attributed to either reduced cohesion of corneocytes or shedding of epidermal cells, rather than breakdown of keratin.

Salicylic acid has no effect on the mitotic activity of normal epidermis and does not influence disordered cornification.[63] It may also provide mild antibacterial value, as it is active against *P. acnes*. It also offers slight antiinflammatory activity at concentrations ranging from 0.5% to 5%. Its efficacy against comedones helps to prevent development of inflamed lesions, thus providing a delayed efficacy.[64]

Salicylic acid is an effective agent. As a peeling agent, its relative strength compared with others in this class varies according to the model used in measurement. It is slightly *less* potent than equal-strength benzoyl peroxide when measured with the rabbit ear animal model, and slightly *more* potent when measured with a biologic microcomedone model.[64] It may have antiinflammatory properties that help dry inflammatory lesions.[62] Its comedolytic properties are considered less potent than topical retinoids. It is often used when patients cannot tolerate a topical retinoid because of skin irritation.[65]

Its keratolytic effect may enhance the absorption of other agents. Salicylic acid may cause some degree of local skin peeling and discomfort (burning or reddening) as it is a mild irritant. It is not a sensitizer. Although the FDA recognizes salicylic acid as safe and effective, the compound offers no advantages over more modern topical agents such as benzoyl peroxide.[61,63,65]

Salicylic acid products are often used as first-line therapy for mild acne because of their widespread availability without a prescription. They are often available in alcohol–detergent impregnated pads as well as washes, bars, and semisolid vehicles. Lower concentrations are sometimes combined with sulfur to produce an additive keratolytic effect. Concentrations of up to 5% to 10% can be used for acne, beginning with a low concentration and increasing as tolerance to the irritation develops. However, the maximum strength allowed in nonprescription acne products is 2%. In high concentrations of 20% to 30% in hydroethanolic vehicles, salicylic acid, either alone or in combination, can be used as a peeling agent for comedonal acne and hyperpigmentation. It has been shown to extrude closed and open comedones several days after peel, but it must be applied under strict control to offer this adjunctive benefit when treating acne vulgaris.[66]

Sulfur. Sulfur medications often lessen the severity of acne, presumably because of keratolytic and antibacterial action. Sulfur helps resolve comedones by its exfoliant action. Its popularity is due to its ability to quickly resolve pustules and papules, mask and conceal lesions (similar to a thick foundation lotion), and produce irritation leading to skin peeling and mild antibacterial action. Sulfur is used in the precipitated or colloidal form in concentrations of 2% to 10%, since it is practically insoluble in water and must be well-dispersed. Its stability depends on effective maintenance of the dispersion.[62] Sulfur compounds (e.g., sulfides, thioglycolates, sulfites, thiols, cysteines, and thioacetates) are also available and somewhat weaker. Sulfur can cause slight ophthalmic and dermatologic irritation, and patients should be cautioned to avoid eye contact. Use should be discontinued if excessive irritation results. Although it is often

combined with salicylic acid or resorcinol to increase its effect, its use is limited by its offensive odor and the availability of more effective agents.[67]

Sulfur has met the criteria of the FDA Advisory Review Panel for nonprescription topical acne products and is considered safe and effective when used alone, although its antibacterial effects were not recognized by this panel. Sodium thiosulfate, zinc sulfate, and zinc sulfide were not considered safe and effective.

Topical Retinoids. Normal epithelial cell differentiation is a vitamin A–dependent process, and the most powerful peeling agents identified to date are related retinoid compounds. The effectiveness of topical retinoids in the treatment of acne is well documented. There is no consensus about the relative efficacy of currently available topical retinoids (tretinoin, adapalene, tazarotene) and oral isotretinoin.

These agents act to reduce obstruction within the follicle and therefore are useful in the management of both comedonal and inflammatory acne. As a group, the retinoids reverse abnormal keratinocyte desquamation.[68] Thus, the retinoid family are highly active peelers. They improve acne vulgaris by inhibiting microcomedone formation, diminishing the number of mature comedones and subsequently, inflammatory lesions. In addition, they normalize follicular epithelium maturation and desquamation. The third-generation retinoids (i.e., adapalene and tazarotene) are receptor specific. Topical retinoids, unlike isotretinoin, do not decrease production of sebum, but primarily decrease inflammation, normalize keratinocyte differentiation, and increase keratinocyte proliferation and migration.[68]

Retinoids have a secondary effect that facilitates acne clearance. By loosening and decreasing corneocytes, they increase skin permeability, facilitate absorption of other agents, such as antimicrobials or benzoyl peroxide, and increase penetration of oral antibiotics into the follicular canal. This decreases the overall duration of antibiotic treatment and lessens the possibility of resistance. Therefore, combination products with oral or topical antimicrobials are available for increased efficacy, faster onset of effects, decreased total antibiotic use and risk of resistance, and shorter duration of treatment.[68] Retinoids may also improve and prevent postinflammatory hyperpigmentation often seen in people with darker complexions who have acne.

Retinoic acid (vitamin A acid or tretinoin) slows the desquamation process, reducing numbers of both microcomedones and comedones.[14] It is a powerful exfoliant and is not to be used in pregnant women because of risk to the fetus. Gels and creams are less irritating than solutions.

Adapalene is a stable, fast-acting, antiacne treatment that has significant antiinflammatory and comedolytic preperties.[68–72] It causes epidermal and follicular epithelium hyperplasia, increased desquamation, keratinocyte differentiation, and loosening of corneocyte connections. Its antiinflammatory effect is due to the inhibition of oxidative metabolism of arachidonic acid and inhibition of chemotactic reponses.[72] It is better at reducing inflammatory lesions and total lesion count[72] and causes less local irritation due to its mechanisms and receptor specificity than tretinoin or tazarotene.[68–75] Release from lotions and hydroalcoholic gels is more effective than from creams and aqueous gels.[68,74] It is a good first-line therapy for colder climates or in patients with sensitive skin.[57]

Tazarotene is also a specific agent with superior efficacy to parent retinoids, reducing both noninflammatory and inflammatory lesions.[68] Its exact mechanism is unknown, but it is thought to activate retinoid receptors and thereby affect keratinocyte differentiation, as well as inhibit proinflammatory transcription factors to decrease cell proliferation and inflammation.[68] It penetrates skin but accumulates in the upper dermis. It is as effective as adapalene in reducing noninflammatory and inflammatory lesion counts when applied half as frequently. Compared with tretinoin, it is as effective for comedonal and more effective for inflammatory lesions when applied once daily.[76–78] Short contact therapy, 1–5 minutes every other night, gradually increasing to overnight, is frequently advocated for dosing in patients with sensitive skin, while oily complexions may tolerate twice daily short contact time. Tazarotene is not degraded by sunlight.[14]

Retinoids include the systemic agent isotretinoin, which has effects on comedogenesis and sebum control, and is reviewed below under Antisebum Agents.

Retinoids tend to produce remissions that are maintained for extended periods of time, provided the accompanying irritation does not impede patient adherence. However, such adverse effects including erythema, xerosis, burning, and desquamation, are issues for many patients. The concentration and/or vehicle of any particular retinoid may decrease tolerability.[69,70] Most retinoids are unstable and insoluble in water.

Topical retinoids are not teratogenic; however, tretinoin should be used cautiously in pregnancy and tazarotene is contraindicated. Tretinoin and adapalene are in FDA category C, while tazarotene, based on large surface area use in psoriasis (see Chap. 107), is in FDA category X.[19]

Application of retinoids should be at night, a half hour after cleansing, starting with every other night for 1 to 2 weeks to adjust to irritation. Short contact time starting with 2 minutes and adding 30 seconds per dose can be advised for patients with sensitive skin or in the winter, discontinuing and resuming after a 3-day rest if undue irritation results. Doses can be increased only after beginning with 4 to 6 weeks of the lowest concentration and least irritating vehicle. Adapalene and tazarotene are photoirritants (not photosensitizers), and sun avoidance and sunscreen use are imperative.[68]

Overall, topical retinoids are the cornerstone of acne treatment and provide safe, effective, and economical means of treating all but the most severe cases of acne vulgaris. They should be the first step in moderate acne, alone or in combination with antibiotics and benzoyl peroxide, reverting to retinoids alone for maintenance once adequate results are achieved.

Antibacterial Agents Choices for antibacterial therapy include benzoyl peroxide, prescription topical and systemic antibiotics, and combination products. These drugs kill *P. acnes* and inhibit the production of proinflammatory mediators by organisms that are not killed.[14]

Benzoyl Peroxide. Benzoyl peroxide is a bactericidal agent that has proven effective in the treatment of acne. Because of concerns of resistance, it is often used in the management of patients treated with oral or topical antibiotics. It is available in a variety of concentrations and vehicles; however, there is insufficient evidence to evaluate and compare the efficacy of these different formulations. It has the ability to prevent or eliminate the development of *P. acnes* resistance.

Benzoyl peroxide is a derivative of coal tar and was first used for acne vulgaris in the mid-1960s, becoming popular once stable formulations aimed at its heat-lability were developed in the mid-1970s.[79] These preparations are the single most useful group of topical nonprescription drugs and agents of first choice for most patients with mild to moderate acne vulgaris. Benzoyl peroxide is well absorbed through the stratum corneum and concentrates in the pilosebaceous unit.[80] It has three principle actions useful in both noninflammatory and inflammatory acne. It produces powerful anaerobic antibacterial activity due to slow release of oxygen, thereby acting against gram-positive and -negative bacteria, yeasts, and fungi. This nonspecific antibacterial mechanism does

not induce resistance with long-term use.[79] It has a rapid (within 2 hours) cidal effect that lasts at least 48 hours. As a result, it may decrease the number of inflamed lesions within 5 days. As an indirect effect, it induces suppression of sebum production; it does not reduce skin surface lipids, but is effective in reducing free fatty acids, which are comedogenic agents and triggers of inflammation.[80] Topical benzoyl peroxide 5% lowers free fatty acids 50% to 60% after daily application for 14 days, and decreases aerobic bacteria by 84% and anaerobic bacteria (primarily *P. acnes*) by 98%. It also produces comedolysis.

While earlier rabbit model studies showed a benzoyl peroxide effect greater than that of salicylic acid, these animal comedones were not physiologic but induced by tar. More recent studies using native microcomedones show an anticomedogenic effect that is only comparatively slight, compared with tretinoin or salicylic acid.[81,82] Finally, a supplementary benefit of benzoyl peroxide is an indirect antiinflammatory action, which is due either to its antibacterial or oxidizing effects. This has been reported in several studies and thus can be used to support treatment of predominantly inflamed lesions.[79] The drug's antiacne effect is augmented by increased blood flow, dermal irritation, local anesthetic properties, and promotion of healing.[83–86] Since the primary effect of benzoyl peroxide is antibacterial, it is most effective for inflammatory acne. Many patients with noninflammatory comedonal acne will respond to its peeling action.

Cleansers containing benzoyl peroxide are available as nonprescription liquid washes and solid bars of various strengths. The desquamative and antibacterial effectiveness in a soap or wash is minimized by limited contact time and removal with proper rinsing. Stable lotions are available in 2.5%, 5%, and 10%. Alcohol and acetone gels facilitate bioavailability and may be more effective, while water-based vehicles are less irritating and better tolerated. A 4% hydrophase gel is available that suspends crystals of benzoyl peroxide in a dimethylisosorbide solvent as the water in the base evaporates. The resulting solution is absorbed by the skin, leaving no film. The manufacturer claims the resulting efficacy is equal to 10% benzoyl peroxide with the minimal irritation of a 2.5% aqueous base gel. This may be an alternative for the patient with easily irritated skin who requires additional potency. This vehicle is easily combined with prepackaged clindamycin or erythromycin powders. Paste vehicles are stiffer and more drying than ointments or creams, which facilitate absorption and allow the active ingredients to stay localized.

Concentrations of 2.5%, 5%, and 10% in a water-based gel have been compared with the vehicle alone. The 2.5% formulation is equivalent to the 5% and 10% formulation in reducing the number of inflammatory lesions. The lower strength may not be as effective a peeler compared to higher strengths, which is due to an irritancy reaction. Thus, irritant side effects with the 2.5% gel are less frequent than with the 10% gel but are equivalent to the 5% gel. The lowest concentration of benzoyl peroxide should be used for treating patients with easily irritated skin and may lessen irritation when used in combination topical therapy with comedolytic agents.

Benzoyl peroxide may bleach hair and clothing. It produces a mild primary irritant dermatitis that subsides with continued use and is more likely to occur in those with fair complexions, a tendency to irritancy, or propensity to sunburn. This irritation is dependent on the concentration and the vehicle, being higher with alcoholic gels compared with emulsion bases.[80] There are rare reports of contact allergic dermatitis. Cross-reactions with other sensitizers, notably Peruvian balsam and cinnamon, are well established. It may cross-sensitize to other benzoic acid derivatives such as topical anesthetics. Concomitant use of an abrasive cleanser may initiate or enhance sensitization.[87]

Another side effect is body odor from breakdown of the benzoyl peroxide that remains on clothing and bed sheets.

There is no indication that the normal use of benzoyl peroxide in the treatment of acne is associated with an increased risk of facial skin cancer. Although links have been made in experiments with mice, human relevance has not been established. The weak in vitro genotoxic potential is not manifested in vivo based on a lack of initiating or complete carcinogenic activity.[80] Overall, the cutaneous use of benzoyl peroxide is relatively safe, and is recognized by the FDA as category 3, which means that more information is required to make a final determination of safety and efficacy for nonprescription use.[88–91] Safety is also confirmed by the American Academy of Dermatology and the German BGA-Monograph.[79]

Benzoyl peroxide has been used in combination with other antiacne medications, such as sulfur and chlorhydroxyquinoline, or in formulations with urea to facilitate drug delivery. No significant improvement has been demonstrated.

Benzoyl peroxide has also been combined with prescription agents to improve efficacy, reduce dosing strengths, decrease irritation, and reduce resistance of antibiotics. [92–94]

A combination of benzoyl peroxide with butenafine, an allylamine, was compared with benzoyl peroxide alone in an open-label, patient-satisfaction, 8-week comparative study of 23 patients with mild to moderate facial acne.[95] The allylamine-benzoyl peroxide combination therapy outperformed benzoyl peroxide action alone during 2-week evaluations in reduction of comedones, inflammatory lesions, and degree of oiliness. There was a marked preference for the allylamine-benzoyl peroxide combination in terms of patient satisfaction, although the patient sample is too small to reach significant conclusions.

The adjunctive use of clindamycin/benzoyl peroxide gel with tazarotene cream promotes greater efficacy and may also enhance tolerability. Increased tolerability might be attributed to emollients in the clindamycin/benzoyl peroxide gel formulation.[96] A patented gel formulation of benzoyl peroxide 5%/clindamycin phosphate 1% (clindamycin) containing dimethicone and glycerin was studied both as a monotherapy and in combination with topical retinoid use. Certain additives, such as silicates and specific humectants, reduced irritation by maintaining barrier integrity.[97]

Preparations of benzoyl peroxide are available without prescription in concentrations up to 5%. Recommend the weakest concentration (2.5%) in a water-based formulation or the 4% hydrophase, for anyone with a history of skin irritation, or who must use combination therapy.[98] There are many suggested routines to initiate therapy. One is to gently cleanse the skin and apply the preparation for 15 minutes the first evening, avoiding the eyes and mucous membranes. A mild stinging and reddening will appear. Each evening the time should be doubled until the product is left on for 4 hours and subsequently all night. Dryness and peeling will appear after a few days. Once tolerance is achieved, the strength may be increased to 5% or the base changed to the acetone or alcohol gels, or to paste. Alternatively, benzoyl peroxide can be applied for 2 hours for 4 nights, 4 hours for 4 nights, and then left on all night. It is important to wash the product off in the morning. Other drying agents should be discontinued. Patients with very sensitive skin or demonstrated sensitivity to benzoyl peroxide should not use the product, and it should be discontinued if irritation becomes severe upon use. Contact with eyes, lips, or mouth should be avoided.

A sunscreen is recommended if benzoyl peroxide is used. To avoid interactions, apply the sunscreen during the day and the benzoyl peroxide at night.

Comparison of Salicylic Acid and Benzoyl Peroxide. While both salicylic acid and benzoyl peroxide are used for mild to moderate acne, their mechanisms differ and therefore different types

of acne respond to each. Benzoyl peroxide is a strong antibacterial agent, while salicylic acid acts primarily through keratolysis.

Studies have shown salicylic acid to be equal or slightly superior to benzoyl peroxide in reducing number of comedones and subsequently number of inflammatory lesions. Any superiority salicylic acid demonstrates is likely because it interferes with an earlier step in pathogenesis—formation of the primary lesion of acne, the microcomedone.[63,65] However, studies of the compound did not use identical formulations. Instead, they compared salicylic acid cleansers to benzoyl peroxide washes and salicylic acid solutions to benzoyl peroxide creams. The effect of different bases is critical in determining differences in efficacy and therefore comparability of action since the base itself has an effect and influences penetration and duration of action.

In summary, the two products have similar efficacy, with salicylic acid noted as stronger in terms of retarding comedone formation. Benzoyl peroxide, as an antibacterial with some peeling effects, is considered the nonprescription and cosmetic gold standard for milder versions of the condition, used alone or in combination to increase efficacy and improve tolerability; however, salicylic acid is included in many of these products because of the perception of efficacy and safety for comedonal acne of type 1 or milder presentation.[64]

Topical Antibacterials. The value of topical antibiotics in the treatment of acne has been investigated in many clinical trials. In addition to reduction of *P. acnes* as the primary mechanism for efficacy in acne, certain antibiotic drugs are also potent antiinflammatory agents via other mechanisms.

Macrolides, including topical erythromycin and topical clindamycin, have been demonstrated to be effective and are well tolerated, well established acne treatments. However, they have become less effective since the early 1990s due to resistance by *P. acnes*.[99] Decreased sensitivity of *P. acnes* to these antibiotics can limit the use of either drug as a single therapeutic agent. Resistant strains are usually resistant to all of the macrolides.

Addition of benzoyl peroxide or topical retinoids to the macrolide antibiotic regimen is more effective than monotherapy and mitigates against survival of resistant *P. acnes* populations. Clindamycin is preferred because of potent action, lack of absorption, and its limited systemic use because it can cause pseudomembranous colitis when given orally or by injection. It is available as a single ingredient topical preparation and can also be combined with benzoyl peroxide.

Erythromycin is available alone and in combination with retinoic acid or benzoyl peroxide.

Some topical antibiotic–benzoyl peroxide combinations require refrigeration.[44]

Oral Antibacterials. Systemic antibiotics are a standard of care in the management of moderate and severe acne and treatment-resistant forms of inflammatory acne. There is evidence to support the use of tetracycline, doxycycline, minocycline, erythromycin, trimethoprim–sulfamethoxazole, trimethoprim, and azithromycin. Studies do not exist for the use of ampicillin, amoxicillin, or cephalexin. However, any antibiotic that can reduce the *P. acnes* population in vivo and interfere with the organism's ability to generate inflammatory agents should be effective.[44] Although erythromycin is effective, use should be limited to those who cannot use one of the tetracyclines (i.e., pregnant women or children under 8 years of age because of the potential for damage to the skeleton or teeth). Ciprofloxacin, trimethoprim–sulfamethoxazole, and trimethoprim alone are also effective in instances where other antibiotics cannot be used or for patients who do not respond to conventional treatment.[61,100]

The tetracycline antibiotic family has multiple modes of action, well understood antibacterial effects, and antiinflammatory effects that target an additional aspect of pathogenesis.[99–101] Agents such as tetracycline, minocycline, and doxycycline are used only as systemic agents. Through calcium chelation, they inhibit neutrophil and monocyte chemotaxis. Doxycycline and minocycline are tenfold more effective than tetracycline, and there is evidence that minocycline is superior to doxycycline in reducing *P. acnes*. Concentrations below the antibiotic threshold still inhibit inflammation, and improve both acne vulgaris and acne rosacea.

Tetracycline is no longer the drug of choice in this family; its disadvantages include diet-related effects on absorption and the drug's lower antiinflammatory and antibacterial activity. Clinically, minocycline appears stronger than doxycycline and will produce a response in patients who do not respond to doxycycline.[99] This may be due to greater lipophilicity; there is a tenfold greater reduction of *P.* acnes by minocycline compared with doxycycline.[102]

Bacterial resistance to antibiotics is an increasing problem particularly because therapy is directed at control over a long period of time.[99] Patients with less severe forms of acne should not be treated with oral antibiotics, and where possible the duration of such therapy should be limited. Resistance has been seen with all antibiotics, but is most common with erythromycin. Resistance is less with tetracyclines than with macrolides, with cross-resistance occurring between tetracycline and doxycycline but not minocycline.[99]

The incidence of significant adverse effects with oral antibiotic use is low. However, adverse effect profiles may be helpful for each systemic antibiotic used in the treatment of acne. Vaginal candidiasis may complicate the use of all oral antibiotics.[44] Doxycycline is very commonly a photosensitizer especially at higher doses. Minocycline has been associated with pigment deposition in the skin, mucous membranes, and teeth, particularly among patients receiving long-term therapy and/or higher doses of the medication. Pigmentation occurs most often in acne scars, anterior shins, and mucous membranes.

Minocycline may cause dose-related dizziness, which resolves with dose titration. Urticaria; autoimmune hepatitis, a systemic lupus erythematosus-like syndrome; and serum sickness-like reactions occur rarely with minocycline.[44,99]

Often, when oral antibiotics are combined with topical agents, the antibiotic may be discontinued after 6 months of therapy.[103] Prolonged oral administration may cause overgrowth of gram-negative organisms, producing a refractory folliculitis and necessitating discontinuation. Regimens should be optimized to minimize antibiotic exposure and reduce resistance. Methods to consider include early use of combination therapy with retinoids. Nearly 70% of patients with acne require antibiotics for 12 weeks or less if aggressive retinoid therapy is used during that time.[99] In addition, initiating use of isotretinoin earlier in indicated patients, rather than prolonging antibiotic courses, and using benzoyl peroxide as part of the regimen when long-term antibiotic therapy is required are two additional strategies to reduce long-term antibiotic use and resistance in acne patients.[99]

Azelaic Acid. Azelaic acid has been shown effective in clinical trials studied with topical 2% erythromycin, topical 5% benzoyl peroxide gel, and topical 0.05% tretinoin cream in the treatment of mild to moderate inflammatory acne. However, the agent has limited efficacy, compared with other antiacne therapies.[44]

Azelaic acid possesses activity against all four pathogenic factors that produce acne. It has antiinflammatory and antibacterial activities. Azelaic acid also normalizes keratinization, which accounts for its anticomedogenic effect. It is a competitive inhibitor of mitochondrial oxidoreductases and of 5-α reductase, inhibiting the conversion of testosterone to 5-dehydrotestosterone. It also possesses bacteriostatic activity to both aerobic and anaerobic bacteria including *P. acnes*. Azelaic acid is an antikeratinizing agent, displaying

antiproliferative cytostatic effects on keratinocytes and modulating the early and terminal phases of epidermal differentiation.[104] It may produce hypopigmentation. Inhibition of thioredoxin reductase by azelaic acid provides a rationale for its depigmenting property.

Azelaic acid 20% cream is used in the treatment of mild to moderate inflammatory acne, has an excellent safety profile with minimal adverse effects, and is well-tolerated in comparison with other acne treatments. The most common adverse effects, occurring in approximately 1% to 5% of patients, are pruritus, burning, stinging, and tingling. Adverse reactions are generally transient and mild in nature. Other adverse reactions, such as erythema, dryness, rash, peeling, irritation, dermatitis, and contact dermatitis, have been reported in less than 1% of patients.[104]

Azelaic acid should be applied twice a day, in the morning and evening. A majority of patients with inflammatory lesions may experience an improvement in their acne within 4 weeks of beginning treatment. However, treatment may be continued over several months, if necessary.

Azelaic acid is in a Pregnancy Category B and should only be used in pregnant women if medically necessary. Patients with dark complexions should be monitored for early signs of hypopigmentation.

Intralesional Steroids. Intralesional corticosteroid injections are effective in the treatment of individual inflammatory acne nodules. The effect of intralesional injection with corticosteroids is a well-established and recognized treatment for large inflammatory lesions. Cystic acne improved in patients receiving intralesional steroids.[44]

Systemic absorption of steroids may occur with intralesional injections. Adrenal suppression was observed in one study. The injection of intralesional steroids may be associated with local atrophy. Lowering the concentration and/or volume of steroid may minimize these complications.

Antisebum Agents No topical agents directly influence the production of sebum. Systemic drugs that influence sebum production include high-dose estrogens, antiandrogens (cyproterone acetate), spironolactone, and the retinoid isotretinoin.

Estrogen-containing oral contraceptives can be useful in the treatment of acne in some women. Oral antiandrogens, such as spironolactone and cyproterone acetate, can also be useful in the treatment of acne. While flutamide can be effective, hepatotoxicity limits its use. There is no evidence to support the use of finasteride. There are limited data to support the effectiveness of oral corticosteroids in the treatment of acne. Oral corticosteroid therapy is of temporary benefit in patients who have severe inflammatory acne. In patients who have well-documented adrenal hyperandrogenism, low-dose oral corticosteroids may be useful in treatment of acne.[44]

Oral Contraceptives. Estrogen-containing contraceptive agents have been studied for the treatment of acne. Those currently approved by the US Food and Drug Administration (FDA) for the management of acne contain norgestimate with ethinyl estradiol and norethindrone acetate with ethinyl estradiol. There is good evidence and consensus opinion that other estrogen-containing oral contraceptives are also equally effective.[44] The effect on acne of other estrogen-containing contraceptives (e.g., transdermal patches, vaginal rings) has not been studied.

Spironolactone. At higher doses, spironolactone is an antiandrogenic compound. Dosages of 50 mg to 200 mg have been shown to be effective in acne. Spironolactone may cause hyperkalemia, particularly when higher doses are prescribed or when there is cardiac or renal compromise. It occasionally causes menstrual irregularity.[105–107]

Cyproterone Acetate. Cyproterone combined with ethinyl estradiol (in the form of an oral contraceptive) has been found effective in the treatment of acne in females. Higher doses have been found more effective than lower doses. No cyproterone/estrogen-containing oral contraceptives are approved for use in the United States.[108]

Oral Corticosteroids. Oral corticosteroids have two potential modes of activity in the treatment of acne. One study demonstrated that low-dose corticosteroids suppress adrenal activity in patients who have proven adrenal hyperactivity.[109] Expert opinion is that short courses of higher dose oral corticosteroids may be beneficial in patients with highly inflammatory disease.

Oral Isotretinoin. Oral isotretinoin is a natural metabolite of vitamin A. Its mechanism is elusive, as it does not bind to retinoid receptors. It has been shown to reduce sebogenesis and may also inhibit sebaceous gland activity, growth of *P. acnes*, inflammation, and improve follicular epithelial differentiation.[110] Systemic isotretinoin exerts a primary effect on comedogenesis, causing a decrease in size and reduction in formation of new comedones.[14] Isotretinoin is the only drug treatment for acne that produces prolonged remission.

Oral isotretinoin is approved for the treatment of severe recalcitrant nodular acne. Oral isotretinoin is also useful for the management of less severe acne that is treatment-resistant (unresponsive to adequate treatment, reasonable courses of antibiotic, or combination peelers and antibiotics administered for 6 weeks to 3 months) or that is producing either physical or psychologic scarring.[44]

The teratogenic effects of oral retinoid therapy are well documented. Because of its teratogenicity and the potential for many other adverse effects, this drug should be prescribed only by those physicians knowledgeable in its appropriate administration and monitoring. Female patients of child-bearing potential must only be treated with oral isotretinoin if they are participating in the approved pregnancy prevention and management program (iPLEDGE). Two different forms of contraception must be started 1 month before and continue at least 1 month (but normally 4 months) after therapy.

The approved dosage of isotretinoin is 0.5 to 2.0 mg/kg/day. The drug is usually given over a 20-week course. Drug absorption is greater when the drug is taken with food. Initial flaring can be minimized with a beginning dose of 0.5 mg/kg/day or less. Alternatively, lower doses can be used for longer time periods, with a total cumulative dose of 120 to 150 mg/kg. In patients with severely inflamed acne, an even greater initial dose reduction may be required. In the most severe cases of acne, consideration of pretreatment with oral corticosteroids may also be appropriate. When used, drying agents must be discontinued, and replaced with moisturizers.

Isotretinoin, a vitamin A derivative, interacts with many of the biologic systems of the body, and consequently has a significant pattern of adverse effects. The pattern is similar to that seen in hypervitaminosis A. Side effects include those of the mucocutaneous, musculoskeletal, and ophthalmic systems, as well as headaches and central nervous system effects. Most of the adverse effects are temporary and resolve after the drug is discontinued. Laboratory monitoring during therapy should include triglycerides, cholesterol, transaminases, and complete blood counts.

Mood disorders, depression, suicidal ideation, and suicides have been reported sporadically in patients taking this drug. However, a causal relationship has not been established. Nonetheless, there are instances in which withdrawal of isotretinoin has resulted in improved mood and reintroduction of isotretinoin has resulted in the return of mood changes. The symptoms mentioned are quite common in adolescents and young adults, the age range of patients who are likely to receive isotretinoin. Treatment of severe acne with isotretinoin is often associated with mood improvement. There is

epidemiologic evidence that the incidence of these events is less in patients treated with isotretinoin than in an age-matched general population. There is also evidence that the risk of depressed mood is no greater during isotretinoin therapy than during therapy of an age-matched acne group treated with conservative therapy. Nonetheless, patients must be made aware of this possibility and treating physicians should monitor patients for psychiatric adverse effects.[44]

Some patients experience a relapse of acne after the first course of treatment with isotretinoin. Relapses are more common in younger adults or when lower doses are used.

Pharmacologic Cleansing Options

Medicated Soaps and Washes. Medicated soaps, washes, and foams may contain topical antiseptics, or peeling agents such as salicylic acid, sulfur, benzoyl peroxide, or clindamycin, alone or in combination in low concentrations, and may be nonprescription or prescription status. Most washes should remain on the skin from 15 seconds to 5 minutes followed by thorough rinsing. This limits the amount of time the active ingredient is in contact with the skin. Other cleansers are applied after washing and left on the skin without rinsing.

Quaternary ammonium compounds are cationic detergents that are inactivated quickly in the presence of organic material, such as sebum. The duration of action of these products is short.

Bacteriostatic soaps, such as hexachlorophene, carbanilides, and salicylanilides (halogenated hydroxyphenols), are acnegenic.[111] Few ordinary soaps induce acne. However, acne patients are particularly susceptible to comedogenic contactants, and if these soaps are applied several times daily for long periods, they may become troublesome.

Soaps containing coal tar, which can induce folliculitis, are not indicated for acne.

Chlorhexidine inhibits in vitro growth of *P. acnes*.[112] A 4% chlorhexidine gluconate preparation in a detergent base has been shown to be as effective as benzoyl peroxide washes in patients with mild acne, and both preparations reduced the number of inflammatory and noninflammatory lesions after 8 and 12 weeks, compared with vehicle alone.[113]

Alcohol-detergent medicated pads, impregnated with salicylic acid 0.5%, have reduced inflammatory lesions and open comedones in mild to moderate acne. This type of medication is less abrasive, not rinsed off, and convenient.[114]

Alcohol-detergent wipes, swabs, or "pledgets" impregnated with antibiotics, such as clindamycin or lincomycin, are available. The antibiotic is deposited in low concentrations on the surface of the skin, and may not penetrate to the depths of the pilosebaceous duct. Although patients may like the convenience and perception of using an active agent, they should not be recommended over simple cleansing.

Abrasives consist of finely divided particles of fused aluminum or plastic together with cleansing and wetting agents. Abrasives peel and remove surface debris and may assist resorption of papules and pustules. Despite vigorous rubbing, removal of comedones is not accomplished. Particles containing active agents, such as sodium tetraborate decahydrate, dissolve on use, and their abrasiveness is therefore limited.[115] The effectiveness of an abrasive cleanser with and without polyethylene granules showed no difference in results in patients with mild to moderate acne. These products are not indicated in most cases but may be used in a patient who responds empirically.[116]

EVALUATION OF THERAPEUTIC OUTCOMES

9 Provide a monitoring framework for patients with acne. Parameters should be monitored by the patient and recorded in a diary. Therapy should be appropriately tapered in response to improvement or resolution. The health care professional should be responsible for ensuring that the treatment plan remains on schedule and is effective with no adverse effects. The patient should be contacted within 2–3 weeks to determine progress.

Acne is poorly understood by adolescents. These patients often lack knowledge of the cause of the disorder and aggravating factors, indications for self-care versus prescription treatment, and concerns regarding safety and duration of treatment and appropriate application of topical agents. Clinicians should review patient understanding of each of these important factors to ensure patient adherence. There is often a need to supplement counseling sessions with written materials to which the patient can refer at home.

MONITORING OF THE PHARMACEUTICAL CARE PLAN

Tables 106–2 and 106–3 provide a guide for monitoring patients with acne. Table 106–2 outlines general effectiveness and safety

TABLE 106-2 Monitoring Therapy for Acne: Parameters and Frequency

Person Responsible and Frequencies for Monitoring:
Patient: daily while on drug therapy; Pharmacist: every 4–8 weeks of therapy or next pharmacy visit

	Short-Term	
	Effectiveness Endpoints (Acne Resolution/Control)	
Parameter	**Time Frame/Degree of Change**	**Actions**
Lesion count	Decrease by 10–25% within 4–8 wks, with control, or more than a 50% decrease within 2–4 months	If endpoints not achieved, refer to a physician for further therapy.
Comedones	Resolve by 3–4 months	
Inflammatory lesions	Resolve within a few weeks	
Anxiety, depression	Achieve control or improvement within 2–4 months	
	Long Term	
Parameter	**Time Frame/Degree of Change**	**Actions**
Progression of severity	No progression of severity	If endpoints not achieved, refer to a physician for further therapy.
Recurrent episodes	Lengthening of acne-free periods throughout therapy	
Scarring or pigmentation	No further scarring or pigmentation throughout therapy	
	Safety Endpoints (Treatment Side Effects)	
Dermatitis, increased dryness, gastrointestinal upset, photosensitivity	No adverse effects	Refer to a physician for alternate therapy, dose reduction, discontinuation or additive palliative treatment or preventative measures for adverse effects.

TABLE 106-3 Monitoring Care Plans for Acne Types I Through IV

Acne Type	Description	Suggested Options	Follow-up Action if Patient Responds	Follow-up Action If Patient Does Not Respond in 3 Months	Adjustment in Therapy If Patient Does Not Respond Adequately to Previous Action
Type I	Mainly comedones with an occasional small inflamed papule or pustule; no scarring present	Topical retinoid is the drug of choice; can also consider benzoyl peroxide or salicylic acid	Continue until lesions are completely cleared and then stop or taper therapy	Treat as Type II acne	
Type II	Comedones and more numerous papules and pustules (mainly facial); mild scarring	Topical retinoid plus benzoyl peroxide, topical or antibiotic	Continue until lesions are completely cleared and then stop or taper therapy	Treat as Type III acne	
Type III	Numerous comedones, papules and pustules, spreading to the back, chest and shoulders, with an occasional cyst or nodule; moderate scarring	Systemic antibiotic plus topical retinoid, or benzoyl peroxide *Or* Topical retinoid plus benzoyl peroxide plus antibiotic	Oral antibiotics typically are prescribed for daily use over 4–6 months, with subsequent tapering and discontinuation as acne improves. Other agents can also be stopped or tapered at this time	Add oral contraceptive or antiandrogen (women only)	Oral isotretinoin (except in women who are or who may become pregnant; consider safety endpoints (potential adverse effects) before initiating therapy
Type IV	Numerous large cyst on the face, neck and upper trunk; sever scarring	Systemic antibiotic plus topical retinoid, and benzoyl peroxide +/- oral contraceptive or anti-androgen (females only)	Oral antibiotics typically are prescribed for daily use over 4–6 months, with subsequent tapering and discontinuation as acne improves Other agents can also be stopped or tapered at this time	If no response after 3–6 months, oral isotretinoin (except in women who are or who may become pregnant) Consider safety endpoints (potential adverse effects) before initiating therapy	

endpoints, monitoring parameters, and degree of change and timeframes for short- and long-term outcomes. Table 106–3 is a guide for monitoring acne patients with consideration to the severity grading of acne types I through IV.

CONCLUSIONS

Considerable gaps remain in the understanding of acne, despite all that is known about the pathogenesis of acne and the mechanisms of effective drugs for controlling its symptoms, progression, and complications at structural, biochemical, and physiologic levels. It is still not possible to precisely define the cause of one of the most common skin diseases, nor is it possible to identify a cure for a condition that affects a very large proportion of the global population.

CHAPTER 107

Psoriasis

REBECCA M. LAW AND WAYNE P. GULLIVER

KEY CONCEPTS[1]

1. Patients with psoriasis have a lifelong illness that may be very visible and emotionally distressing. There is a strong need for empathy and a caring attitude in interactions with these patients.
2. Psoriasis is a T-lymphocyte–mediated inflammatory disease that results from a complex interplay between multiple genetic factors and environmental influences. Genetic predisposition coupled with some precipitating factor triggers an abnormal immune response, resulting in the initial psoriatic skin lesions. Keratinocyte proliferation is central to the clinical presentation of psoriasis.
3. Diagnosis of psoriasis is usually based on recognition of the characteristic psoriatic lesion and not based on laboratory tests.
4. Treatment goals for patients with psoriasis are to minimize signs such as plaques and scales, alleviate symptoms such as pruritus, reduce the frequency of flare-ups, ensure appropriate treatment of associated conditions such as psoriatic arthritis or clinical depression, and minimize treatment-related morbidity.
5. Management of patients with psoriasis generally involves both nonpharmacologic and pharmacologic therapies.
6. Nonpharmacologic alternatives such as stress reduction and the liberal use of moisturizers may be very beneficial and should always be considered and initiated when appropriate.
7. Pharmacologic alternatives for psoriasis include topical agents, phototherapy, and systemic agents (both traditional agents and newer biologic response modifiers).
8. In initiating pharmacologic treatment, the choice of therapy is generally guided by the severity of disease. Topical agents are appropriate for mild to moderate disease, while systemic agents are better choices for moderate to severe disease. Phototherapy or photochemotherapy are used for patients with moderate to severe psoriasis, generally when topical therapies alone are inadequate. Patient-specific concerns such as existing comorbid conditions (e.g., diabetes mellitus, hypertension, renal impairment, or hepatic disease) must also be taken into consideration in the choice of therapy. Once the disease is under control, therapy should be stepped down to the least potent, least toxic agent(s) that maintain control.
9. Rotational therapy (i.e., rotating systemic drug interventions) is a means to minimize drug-associated toxicities. However, continuous treatment has replaced rotational or sequential therapy and is now the standard of care for many dermatologists.
10. Some biologic response modifiers have proven efficacy for psoriasis; however, there are differences among these agents, including mechanism of action, duration of remission, and adverse-effect profile. In general, due to their immunomodulatory effects, risk of infection is increased with most of these agents. The use of live or live-attenuated vaccines during therapy is generally contraindicated. Currently, biologic response modifiers are often considered for patients with moderate to severe psoriasis when other systemic agents are inadequate or relatively contraindicated. It has also been recommended that biologic response modifiers be considered as first-line therapy, alongside conventional systemic agents, for patients with moderate to severe psoriasis; however, in practice, drug access due to cost considerations may be a limiting factor. They may be appropriate if comorbidities exist.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Psoriasis is a chronic disease that waxes and wanes. It is never cured, and it is now known to be associated with multiple comorbidities including heart disease, diabetes, and the metabolic syndrome. The signs and symptoms of psoriasis may subside totally (go into remission) and then flare-up again (exacerbation). Triggers include stress, seasonal changes, and some drugs. Disease severity may vary from mild to disabling. Psoriasis imposes a burden of disease that extends beyond the physical dermatologic manifestations.

1 Patients with psoriasis have a lifelong illness that may be very visible and emotionally distressing. There is a strong need for empathy and a caring attitude in interactions with these patients. Thus, management of this condition is necessarily long-term and multifaceted, and management modalities may change according to the severity of illness at the time.

EPIDEMIOLOGY

Psoriasis is likely the most common immune modulated inflammatory disease in North America and Europe, as it is thought to affect 17 million people, or about 2% of the population.[2,3] Worldwide prevalences vary between 0.1% and 3%, with reasons for variation ranging from racial to geographic and environmental.[3] Higher prevalences than 3% have been reported occasionally in Canada and the United States. Lower frequencies of between 0.4% and 0.7% are seen for people of African and Asian descent.[4,5] Of interest is the fact that

psoriasis is seldom seen in North and South American Aboriginal Indians. It affects males and females equally.[3,6] The majority of patients (approximately 75%) have onset before the age of 40,[3] but psoriasis has been observed at birth and as late as the ninth decade of life.[3] Many studies report two peak ages of onset: at 20 to 30 and 50 to 60 years of age.[3,5]

ETIOLOGY

2 Psoriasis is a T-lymphocyte–mediated inflammatory disease that results from a complex interplay between multiple genetic factors and environmental influences. Genetic predisposition coupled with some precipitating factor triggers an abnormal immune response, resulting in the initial psoriatic skin lesions. Keratinocyte proliferation is central to the clinical presentation of psoriasis.

GENETICS

Dermatologists have recognized the familial tendencies of psoriasis for many years. Monozygotic twins have a concordance rate in the 80% range. Rates of family history in a psoriasis family range between 36% and 91%.[6–9] A study utilizing the founder population of Newfoundland and Labrador noted that more than 80% of the patients had a positive family history.

Genetic studies suggested at least seven loci are involved in psoriasis.[3] In 2009, studies of the Newfoundland and Labrador population confirmed that major histocompatibility complex antigen HLA-Cw6 and tumor necrosis factor (TNF)-α as major psoriasis susceptibility genes, along with IL-23 loci that had previously been reported.[3,10] The findings have recently been confirmed in multiple populations from North America, Europe, and China.[11,12]

PREDISPOSING FACTORS AND PRECIPITATING FACTORS

Injury to the skin, infection, drugs, smoking, alcohol consumption, obesity, and psychogenic stress have been implicated in development of psoriasis. Examples of these precipitating factors include a horse-fly bite causing skin trauma (known as the *Koebner phenomenon*),[13] a viral or streptococcal infection, or the use of β-adrenergic blockers.[14] Factors exacerbating preexisting psoriasis include drugs [e.g., lithium, nonsteroidal antiinflammatory drugs (NSAIDS), antimalarials, β-adrenergic blockers, and withdrawal of corticosteroids], and psoriatic patients commonly have exacerbations during times of stress.[1,14] Stressful situations occur for many patients, and it is thought that patients with a genetic predisposition to psoriasis and a precipitating event or trigger factor plays a role.

PATHOPHYSIOLOGY

Psoriasis is a common chronic inflammatory disease of the skin that most likely involves both acquired and innate immunity. The interaction between dermal dendritic cells activated T cells of the TH-1, TH-17 lineage in concert with a multitude of cytokines and growth factors are responsible for the epidermal hyperplasia and dermal inflammation that is seen in psoriasis. These inflammatory cells form lymphoid structures in psoriatic dermis, allowing the unimpeded inflammatory process to continue.[15] When therapeutic intervention is initiated and positive the psoriatic phenotype is completely reversible without residual damage. This is in contrast to significant damage often seen in psoriatic arthritis that, if not treated early, is irreversible.

COMORBIDITIES

It is now well documented that psoriasis patients have significant associated comorbidities. Psoriatic arthritis is one of the most common and well-known extracutaneous manifestations of disease. Other associated comorbidities include metabolic syndrome, other immune-mediated disorders such as Crohn's disease, multiple sclerosis, and some psychological illnesses (anxiety, depression, and alcoholism).[16] Also, malignancies such as cutaneous T-cell lymphoma are associated with psoriasis and melanoma and nonmelanoma skin cancer are associated with psoriasis treatments.

The National Psoriasis Foundation published a clinical consensus on psoriasis comorbidities with recommendations for screening and addressing issues such as cardiovascular risk, metabolic syndrome, and obesity.[17] The importance of screening for comorbidities in psoriasis patients cannot be overemphasized: Nearly half of the psoriatic patients over age 65 have at least three comorbidities, (with two thirds of this patient population having two or more comorbidities).[18] The presence of a specific comorbidity in a patient with psoriasis may influence the choice of pharmacotherapy.

Psoriatic arthritis (PsA) usually develops after the onset of psoriasis,[3] typically 10 years later.[16] However, 10% to 15% of patients report that the PsA appeared first.[3] The prevalence of PsA in psoriatic patients is about 30% but varies by disease severity.[16] In one U.S. study, the prevalences were 14% for patients with mild psoriasis, 18% for those with moderate psoriasis, and 56% for patients with severe psoriasis.[19] TNF-α and HLA-Cw6 are linked to both PsA and psoriasis.[20] Although immunomodulating treatments for psoriasis (such as methotrexate or TNF-α inhibitors) are useful for PsA, NSAIDs effective for joint symptoms of PsA may exacerbate psoriasis.

Metabolic syndrome is a cluster of risk factors including abdominal obesity, atherogenic dyslipidemia, hypertension, insulin resistance or glucose intolerance, prothrombotic state, and proinflammatory state.[17] Patients with psoriasis are at increased risk of developing metabolic syndrome.[17] The syndrome is a strong predictor of cardiovascular diseases, stroke, and diabetes.[17,21,22] Patients with this syndrome are three times as likely to have a myocardial infarction (MI) or stroke, twice as likely to die from the MI or stroke, and five times as likely to develop type 2 diabetes.[17]

Patients with psoriasis also have a decreased life expectancy and increased rates of mortality. Psoriasis is an independent risk factor for atherosclerosis, especially for younger patients with severe disease.[17] A 2006 study found that a relative risk (RR) of death for a 30-year-old person with severe psoriasis was 3.10, after controlling for traditional cardiovascular risk factors[e.g. age, gender, hypertension, dyslipidemia, diabetes mellitus, smoking, body mass index (BMI), C-reactive protein (CRP), and family history of cardiovascular disease].[17,22]

TYPES OF PSORIASIS

Plaque psoriasis, also known as *psoriasis vulgaris*, is the most common type of psoriasis (Table 107–1) and is seen in about 90% of

psoriasis patients. Plaque psoriasis presents as shown in the Clinical Presentations box.

CLINICAL PRESENTATION

Signs and Symptoms of Plaque Psoriasis	Description (From Reference 23)
Lesions (plaques)	Erythematous Red-violet in color At least 0.5 cm in diameter Well demarcated—clearly distinguished from normal skin Typically covered by silver, flaking scales
Skin involvement	Either as single lesions at predisposed areas (e.g., knees, elbows) or Generalized over a wide body surface area (BSA) Mild psoriasis: ≤5% BSA involvement Moderate psoriasis: PASI ≥8 (higher in trials of biologics) Severe psoriasis: The rule of tens: PASI ≥10 or DLQI ≥10 or BSA ≥10% (in some phototherapy trials, BSA ≥20% used as lower limit)
Pruritus	More than 50% of patients with psoriasis have associated pruritus May be severe in some patients and may require treatment to minimize excoriations from constant scratching
Other associated concerns	Lesions may also be physically debilitating or socially isolating. Potential comorbidities: PsA, depression, hypertension, obesity, diabetes mellitus, Crohn's disease, anxiety, alcoholism

DIAGNOSTIC CONSIDERATIONS

3 The diagnosis of psoriasis is a diagnosis based upon recognition of the characteristic psoriatic lesion and not on laboratory tests. Diagnostic testing is rarely performed as a biopsy may be suggested but is not diagnostic of psoriasis.

Psoriasis is classified into mild, moderate, or severe. In clinical practice, assessment of the severity of disease includes both an objective evaluation of the extent and symptoms as well as a subjective evaluation of the impact of disease on the patient's quality of life.[23] Assessment typically includes measures of symptom and involvement such as body surface area (BSA), Psoriasis Area and Severity Index (PASI), or Physician's Global Assessment (static PGA), as well as quality-of-life measures such as the Dermatology Life Quality Index (DLQI) or the Short Form (SF-36) Health Survey.[23]

Classification of psoriasis as mild, moderate, or severe disease is generally based on BSA or PASI measurements (see Clinical Presentations box). Practically, to give a rough estimate of BSA involvement, palm size is approximately 1% BSA, head and neck involvement is about 10% BSA, both upper limbs about 20% BSA, trunk involvement (front and back) about 30% BSA, and both lower limbs about 40% BSA.

TREATMENT

Treatment of psoriasis is based on managing the underlying pathophysiology. Agents that modulate the abnormal immune response, such as corticosteroids and biologic response modifiers, are important treatment strategies for psoriasis. Topical therapies that affect cell turnover are also effective for psoriasis. In addition, nonpharmacologic therapies are effective adjuncts and should be considered for all patients with psoriasis. A treatment regimen should always be individualized, taking into consideration severity of disease, patient responses, and tolerability to various interventions. Furthermore, if they exist, comorbidities must be taken into treatment considerations. Optimal psoriasis care needs to maintain a focus on the patient's overall health-related quality of life.

DESIRED OUTCOMES

4 Goals of treatment[1]:

- Minimizing or eliminating the signs of psoriasis such as plaques and scales
- Alleviating pruritus and minimizing excoriations
- Reducing the frequency of flare-ups
- Ensuring appropriate treatment of associated conditions such as PsA, hypertension, dyslipidemia, diabetes, clinical depression, or itching
- Avoiding or minimizing adverse effects from topical or systemic treatments used
- Providing cost-effective therapy
- Providing guidance or counseling as needed (e.g., stress-reduction techniques)
- Maintaining or improving the patient's quality of life

GENERAL APPROACH TO TREATMENT

5 Management of patients with psoriasis generally involves both nonpharmacologic and pharmacologic therapies. Nonpharmacologic therapies are important and should be used for all patients with psoriasis, regardless of the severity of disease. Pharmacologic therapies are always tailored to the individual patient with psoriasis and different treatment strategies would be used depending on psoriatic disease severity, presence or absence of comorbid illnesses, and any special considerations such as hepatic or renal dysfunction.

NONPHARMACOLOGIC THERAPY

6 Nonpharmacologic alternatives may be very beneficial and should always be considered and initiated when appropriate.[1] These include stress-reduction strategies, moisturizers, oatmeal baths, and skin protection using sunscreens.[24]

In particular, stress reduction has been shown to improve both the extent and severity of psoriasis and to include methods such as guided imagery and stress-management clinics. Liberal use of nonmedicated moisturizers, applied ad lib, helps to maintain skin moisture, reduces skin shedding, controls associated scaling, and may reduce pruritus. Oatmeal baths further reduce pruritus and with regular use may minimize the need for systemic antipruritic drugs.

Sunscreens, preferably with a sun protection factor (SPF) of 30 or more, should be regularly used since sunburns can trigger an exacerbation of psoriasis. Irritation to the skin should be minimized—harsh soaps or detergents should not be used. Cleansing should be done with tepid water and preferably with lipid-free and fragrance-free cleansers.[1,24]

PHARMACOLOGIC THERAPY

7 Pharmacologic alternatives for psoriasis are topical agents, phototherapy, and systemic agents, including biologic response modifiers.

Drug Treatments of First Choice

8 For limited or mild to moderately severe disease, topical treatments are the usual standard of care, with phototherapy and photochemotherapy used in moderate to severe cases. For patients presenting with extensive or moderate to severe disease, systemic therapies with or without the use of topical treatments are the usual standard of care. Newer systemic treatments such as biologic response modifiers (BRMs) may be the treatments of choice, especially for patients with comorbidities such as PsA or if traditional systemic treatments (such as methotrexate or cyclosporine) are contraindicated. Once the disease is under control, it would be important to step down to the least potent, least toxic agent(s) that maintain control. 9 Sequential therapy and rotational therapy may minimize drug-associated toxicities; however, continuous treatment is now the standard of care for many dermatologists. Different treatment algorithms are used, depending on the severity of the plaque psoriasis (Figs. 107–1 and 107–2).[1]

Published Guidelines or Treatment Protocols Treatment guidelines have recently been updated in both the United States and Canada.[23,25–32] All U.S. guidelines are endorsed by the American Academy of Dermatology or the National Psoriasis Foundation, and Canadian guidelines are endorsed by the Canadian Dermatology Association. These guidelines represent the current standards of care.

Topical Therapies

Approximately 80% of patients with psoriasis have mild to moderate disease,[27] and the majority of these patients can be treated with topical therapies alone.[27] Individualized approaches are essential because of the wide variation in patients' presentations, their psychosocial health, and their personal opinions as to what would be acceptable treatment.[23] Topical therapies include corticosteroids, vitamin D3 analogues, retinoids, anthralin, and coal tar. These are generally efficacious and safe for this patient population. Topical agents are also used as adjunctive therapy for patients with more extensive disease who are being treated concurrently with phototherapy or systemic agents.

To determine the quantity of topical agents required, the fingertip unit[33] can be used. One fingertip unit is approximately 500 mg,[27,33] which is sufficient to cover one hand (front and back) or about 2% BSA.[34] The trunk (front and back) is about 30% BSA; to cover the entire trunk once, about 15 fingertip units, or 7500 mg (7.5 g), would be required.

Corticosteroids Topical corticosteroids have been the mainstay of therapy for the majority of patients with psoriasis for over half a century. They are generally well tolerated, although adverse effects can occur, including systemic ones. Table 107–2 provides a summary of topical corticosteroid formulations—including ointments, creams, gels, foams, lotions, sprays, shampoos, tape, and solutions[27]—and potencies.

The choice of vehicle affects corticosteroid potency: Ointments, being the most occlusive, enhance drug penetration and provide the most potent formulations. However, patients may prefer a less greasy formulation, such as a cream or lotion for daytime use, although they may be willing to apply the more effective ointment-based corticosteroid during the night.[27] Providing additional occlusion will increase drug penetration of a topical preparation, resulting in enhanced potency. For example, flurandrenolide cream and lotion are potency class 5, but flurandrenolide tape was found to have higher efficacy than diflorasone diacetate ointment (potency class 1).[27,35]

Despite their widespread use, there have been few large-scale, randomized placebo-controlled corticosteroid trials and even fewer head-to-head comparisons with other therapies. The most comprehensive review to date is the analysis of topical psoriasis therapies done in 2002.[23,36] This systemic review found that all topical corticosteroid treatments considered were efficacious and significantly better than placebo and that the highest potency corticosteroids were the most efficacious, followed by vitamin D3 analogues.[23]

Corticosteroids have antiinflammatory, antiproliferative, immunosuppressive, and vasoconstrictive effects.[27] These are mediated through a variety of mechanisms. Mechanisms of action include binding to intracellular corticosteroid receptors and regulation of gene transcription (in particular those which code for proinflammatory cytokines).[27]

Appropriate use of topical corticosteroids should include an assessment of disease severity and disease location as well as knowledge of the patient's preference and age. Lower potency corticosteroids should be used for infants and for lesions on the face, intertriginous areas, and areas with thin skin. For other areas of the body in adults, mid- to high-potency agents are generally recommended as initial therapy.[27] The highest potency corticosteroids are generally reserved for patients with very thick plaques or recalcitrant disease, such as plaques on palms and soles. The use of potency class 1 corticosteroids should be limited to a duration of 2 to 4 weeks,[27] recognizing that the risk of cutaneous and systemic side effects increases with continued use.

TABLE 107-2 Topical Corticosteroid Potency Chart

Potency Rating	Corticosteroid–Topical Preparations
Class 1: Superpotent	Betamethasone dipropionate 0.05% ointment (Diprolene and Diprosone ointment)
	Clobetasone propionate 0.05% lotion/spray/shampoo (Clobex lotion/spray/shampoo, OLUX foam)
	Clobetasone propionate 0.05% cream and ointment (Cormax, Temovate)
	Diflorasone diacetate 0.05% ointment (Florone, Psorcon)
	Halobetasol propionate 0.05% cream and ointment (Ultravate)
	Flurandrenolide tape 4 mcg/cm^2 (Cordran)
Class 2: Potent	Amcinonide 0.1% ointment (Cyclocort ointment)
	Betamethasone dipropionate 0.05% cream/gel (Diprolene cream, gel, and Diprosone cream)
	Desoximetasone 0.25% cream (Topicort)
	Fluocinonide 0.05% cream, gel, ointment (Lidex)
	Halcinonide 0.1% cream (Halog)
Class 3: Upper mid-strength	Amcinonide 0.1% cream (Cyclocort cream)
	Betamethasone valerate 0.1% ointment (Betnovate/Valisone ointment)
	Diflorasone diacetate 0.05% cream (Psorcon cream)
	Fluticasone propionate 0.005% ointment (Cutivate ointment)
	Mometasone furoate 0.1% ointment (Elocon ointment)
	Triamcinolone acetonide 0.5% cream and ointment (Aristocort)
Class 4: Mid-strength	Betamethasone valerate 0.12% foam (Luxiq)
	Clocortolone pivolate 0.1% cream (Cloderm)
	Desoximetasone 0.05% cream and gel (Topicort LP)
	Fluocinolone acetonide 0.025% ointment (Synalar ointment)
	Fluocinolone acetonide 0.2% cream (Synalar-HP)
	Hydrocortisone valerate 0.2% ointment (Westcort ointment)
	Mometasone furoate 0.1% cream (Elocon cream)
	Triamcinolone acetonide 0.1% ointment (Kenalog)
Class 5: Lower mid-strength	Betamethasone dipropionate 0.05% lotion (Diprosone lotion)
	Betamethasone valerate 0.1% cream and lotion (Betnovate/Valisone cream & lotion)
	Desonide 0.05% lotion (DesOwen)
	Fluocinolone acetonide 0.01% shampoo (Capex shampoo)
	Fluocinolone acetonide 0.01%, 0.025%, 0.03% cream (Synalar cream)
	Flurandrenolide 0.05% cream and lotion (Cordran)
	Fluticasone propionate 0.05% cream and lotion (Cutivate cream and lotion)
	Hydrocortisone butyrate 0.1% cream (Locoid)
	Hydrocortisone valerate 0.2% cream (Westcort cream)
	Prednicarbate 0.1% cream (Dermatop)
	Triamcinolone acetonide 0.1% cream and lotion (Kenalog cream and lotion)
Class 6: Mild	Alclometasone dipropionate 0.05% cream and ointment (Aclovate)
	Betamethasone valerate 0.05% cream and ointment
	Desonide 0.05% cream, ointment, gel (DesOwen, Desonate, Tridesilon)
	Desonide 0.05% foam (Verdeso)
	Fluocinonide acetonide 0.01% cream and solution (Synalar)
	Fluocinonide acetonide 0.01% FS oil (Derma-Smoothe)
Class 7: Least Potent	Hydrocortisone 0.5%, 1%, 2%, 2.5% cream, lotion, spray, and ointment (various brands)

Adapted from The National Psoriasis Foundation–Mild Psoriasis: Steroid potency chart, http://www.psoriasis.org/netcommunity/sublearn03_mild_potency. Rosso JD, Friedlander SF. Corticosteroids: Options in the era of steroid-sparing therapy. J Am Acad Dermatol 2005;53:S50–S58; Leung DYM, Nicklas RA, Li JT, et al. Disease management of atopic dermatitis: An updated practice parameter. Ann Allergy Asthma Immunol 2004;93:S1–S17.

Cutaneous adverse effects include skin atrophy, acne, contact dermatitis, hypertrichosis, folliculitis, hypopigmentation, perioral dermatitis, striae, telangiectases, and traumatic purpura.[23,27] Systemic adverse effects have been reported not only with superpotent corticosteroids but also with extended or widespread use of mid-potency agents.[27] Systemic adverse effects include hypothalamic–pituitary–adrenal (HPA) axis suppression and less commonly Cushing syndrome, osteonecrosis of the femoral head, cataracts, and glaucoma.[27]

All topical corticosteroids are pregnancy category C.[27]

Tachyphylaxis can occur with prolonged use, although its clinical significance is difficult to verify.[23] It is recommended that the frequency of use be gradually reduced once clinical response is seen, although there are no established tapering regimens.[27] Other approaches include transitioning to weaker potency agents or combination with other nonsteroidal topical therapies.[27] Pulse dosing has also been used to minimize tachyphylaxis and adverse effects.[37]

Vitamin D3 Analogues Topical vitamin D3 analogues include calcipotriol (calcipotriene), calcitriol (the active metabolite of vitamin D), and tacalcitol. Only calcipotriol is currently available in the United States[27] and Canada.[23] Other analogues currently under study include maxacalcitol and becocalcidiol.[27] Their mechanisms of action include binding to vitamin D receptors, which results in inhibition of keratinocyte proliferation and enhancement of keratinocyte differentiation.[23,27] They also inhibit T-lymphocyte activity.[23]

The efficacy of calcipotriol for patients with mild psoriasis is well established in randomized double-blind placebo-controlled trials. In head-to-head comparison studies with other topical agents, calcipotriol was found to be more effective than anthralin (dithranol)[38] and comparable or slightly more effective than potency class 3 (upper mid-strength) topical corticosteroid ointments such as betamethasone valerate 0.1% ointment.[23,39,40] In an analysis of topical psoriasis therapies done in 2002,[37] calcipotriol was found to be as effective as all but the most potent topical corticosteroids.[23]

Vitamin D3 analogues are generally well tolerated and have a good safety profile in comparison with other topical therapies.[41] Cutaneous adverse effects most commonly include a mild irritant contact dermatitis; others include burning, pruritus, edema, peeling, dryness, and erythema.[23,27] These adverse effects may be mitigated with continued use.[27] Systemic adverse effects, including hypercalcemia and parathyroid hormone suppression, are rare unless patients are using more than the recommended maximum of 5 mg calcipotriol (100 g of calcipotriol 50 mcg/g cream or ointment) per week[23,27] or if there is underlying renal disease or impaired calcium metabolism.[27]

Calcipotriol is pregnancy category C. It is inactivated by ultraviolet A (UVA) light thus it should be applied after rather than before UVA exposure.[27]

Retinoids Tazarotene is a topical retinoid that acts through the following mechanisms: normalizing abnormal keratinocyte differentiation, diminishing keratinocyte hyperproliferation, and clearing the inflammatory infiltrate in the psoriatic plaque.[23,27] It is effective in clearing psoriatic plaque lesions and achieving remission.

In a placebo-controlled trial of tazarotene 0.1% and 0.05% gels for patients with plaque psoriasis, tazarotene provided a 50% or greater improvement in 63% (0.1% gel) and 50% (0.05% gel) of patients, respectively, after 12 weeks of use.[42] The therapeutic benefit appears to be maintained for 12 weeks after cessation of therapy.[42] Later clinical trials with tazarotene 0.1% and 0.05% creams versus a placebo vehicle provided similar findings.[43]

Adverse effects of tazarotene include a high incidence of irritation at the site of application, a dose-dependent effect.[23] This results in burning, itching, and erythema, which can occur in lesional and perilesional skin.[27] Irritation may be reduced by using the cream formulation, lower concentration, alternate-day application, or short-contact (30 to 60 minutes) treatment.[27] Ad lib use of moisturizers is also beneficial. Tazarotene is also potentially photosensitizing, due to thinning of the epidermis that can occur with continued use.[27]

Tazarotene is pregnancy category X and should not be used in women of childbearing age unless effective contraception is being used.

Anthralin Anthralin is not as commonly used as other topical therapies currently available for psoriasis; however, there are situations where its use is appropriate and efficacious. It has a direct antiproliferative effect on epidermal keratinocytes,[1,14] normalizing keratinocyte differentiation.[27] Although the exact mechanism of action is unknown, it may have a direct effect on mitochondria[27,44] and reduce the mitotic activity. It also prevents T-lymphocyte activation.[27] Small placebo-controlled studies demonstrated efficacy for anthralin used continuously or as very short contact (1 minute of treatment).[27]

Currently, short-contact anthralin therapy (SCAT) is usually the preferred regimen, where the anthralin ointment is applied only to the thick plaque lesions for 2 hours or less and then wiped off.[1,27] Since lesions are generally well demarcated, zinc oxide ointment or a nonmedicated stiff paste should be applied to the surrounding normal skin to protect it from irritation and burning. Anthralin should be used with caution, if at all, on the face and intertriginous areas due to the risk of severe skin irritation.[27]

Concentrations for SCAT range from 1% to 4% or as tolerated; concentrations for continuous anthralin therapy vary from 0.05% to 0.4%. Aside from significant and often severe skin irritation, other adverse effects include folliculitis and allergic contact dermatitis, but these are uncommon.

Anthralin is Pregnancy Category C. People who handle the dry anthralin powder should avoid skin contact (e.g., by wearing gloves while compounding).[1]

Coal Tar Coal tar was one of the earliest agents used to treat psoriasis. It is keratolytic and may have antiproliferative and anti-inflammatory effects.[1] Coal tar formulations include crude coal tar and tar distillates (liquor carbonis detergens) in ointments, creams, and shampoos. Due to limited efficacy coupled with patient acceptance/compliance issues, coal tar preparations are less commonly used today, especially in North American countries.

A 2007 comparative study in Thailand reported that betamethasone valerate was significantly more effective than coal tar.[23,45] Although coal tar may have similar efficacy as calcipotriol, it has a slower onset of action.[22] In addition, coal tar has an unpleasant odor and will stain clothing; thus, it may be cosmetically unappealing to patients.

Adverse effects include folliculitis, acne, local irritation, and phototoxicity.[23] It is carcinogenic in animals, but for humans no convincing data have emerged regarding carcinogenicity with topical use.[27]

Coal tar concentrations as used in psoriasis treatments (0.5% to 5%) are considered safe by the FDA.[30] However, occupational exposure to coal tar, especially in very high concentrations such as coal tar used in industrial paving,[30] was reported to increase the risk of lung cancer, scrotal cancer, and skin cancer.[27,30] The risk of teratogenicity when used in pregnancy is likely to be small, if it exists.[27]

Salicylic Acid Salicylic acid has keratolytic properties and has been used in various formulations including shampoos or bath oils for patients with scalp psoriasis. In combination with topical corticosteroids, it enhances steroid penetration thus increasing efficacy. It should not be used in combination with ultraviolet B (UVB) phototherapy due to a filtering effect that may reduce efficacy. Systemic absorption and toxicity can occur, especially when applied to more than 20% BSA or when used for patients with renal impairment.

Avoid the use of salicylic acid in children. However, it may be used for limited and localized plaque psoriasis in pregnancy.[27]

Calcineurin Inhibitors Topical calcineurin inhibitors such as pimecrolimus 1% cream (Elidel) are used for the treatment of inflammatory skin diseases such as atopic dermatitis.[46–48] Pimecrolimus was found to be effective for plaque psoriasis when used under occlusion[47] and also effective for patients with moderate to severe inverse psoriasis (intertriginous areas are affected).[48] Since this cream is less irritating than calcipotriol and also avoids steroid adverse effects such as skin atrophy, it may be a useful alternative for patients with lesions in intertriginous areas.

Phototherapies and Photochemotherapy

Phototherapy has been used for treating psoriasis for years and is still an important treatment modality today. It has been known for centuries that some skin diseases improve with sun exposure, and clinical studies with phototherapies have been reported since the late 19th century.[25] Phototherapy consists of using nonionizing electromagnetic radiation, either UVA or UVB, as light therapy to treat psoriatic lesions.[49]

UVB is given alone as either broadband or narrowband UVB (NB-UVB), currently with NB-UVB being the preferred method. Broadband UVB is also given as photochemotherapy with topical agents such as crude coal tar (Goeckerman regimen)[49] or anthralin (Ingram regimen) for enhanced efficacy.[25]

UVA is generally given with a photosensitizer, such as an oral psoralens, to enhance efficacy—this regimen is known as PUVA.[49]

With respect to comparative efficacy, NB-UVB is more efficacious than broadband UVB, but may be slightly less effective than PUVA.[25,28] PUVA is very effective in the majority of patients, with

the potential for long remissions.[28] However, due to greater availability of UVB treatment centers, more evidence of the efficacy of UVB treatments for psoriasis (in particular, NB-UVB), and especially the increasing concerns about PUVA toxicities (including skin cancers), phototherapy for psoriasis currently uses UVB or NB-UVB where available. Failure of NB-UVB may justify PUVA therapy.[49]

UVB interferes with protein and nucleic acid synthesis, leading to decreased proliferation of epidermal keratinocytes.[25] UVA has similar effects on epidermal keratinocytes. However, because of deeper penetration into the dermis, it also has effects on dermal dendritic cells, fibroblasts, endothelial cells, mast cells, and skin-infiltrating inflammatory cells including granulocytes and T lymphocytes.[25]

Adverse effects of phototherapy include erythema, pruritus, xerosis, hyperpigmentation, and blistering, especially with higher dosages. It should be used with caution for patients with photosensitivity concerns, and drug interactions include photosensitizing medications such as tetracyclines. Patients must be provided with eye protection during UVB, NB-UVB, or PUVA treatments, and for 24 hours[49] or the remainder of the day[25] after PUVA treatments. In addition, patients receiving PUVA therapy may experience gastrointestinal symptoms such as nausea or vomiting, which may be minimized by taking the oral psoralens with food or milk.[25] For patients also receiving oral retinoids (RE-PUVA), the UVA dose should be reduced by one third.[25]

Long-term PUVA use can lead to photoaging and the development of PUVA lentigines. Psoralens bind to proteins in the lens of the eye; thus, there is a potential for increased cataract formation. Furthermore, although UVB has a theoretical risk of photocarcinogenesis, the risk is significantly higher with PUVA and is dose related.[25,49] A metaanalysis reported a 14-fold increase in the incidence of squamous cell carcinoma (SCC) in patients receiving high-dose PUVA when compared with low-dose PUVA, with SCC of the male genitalia particularly elevated.[25,50] PUVA may also increase the risk of basal cell carcinoma and possibly melanoma,[25] which may occur 15 years after the first treatment.[49]

Systemic Therapies

Systemic therapies are the mainstay of treatment for patients with moderate to severe psoriasis, with topical therapies remaining as useful adjuncts. However, as discussed below under combination therapies, topical calcipotriol and betamethasone dipropionate ointment may provide sufficient disease control for some patients.[23,51] Conversely, a subset of patients with limited disease may have debilitating symptoms, and the use of systemic therapies would be warranted.[26] Systemic therapies include the following traditional agents acitretin, cyclosporine, methotrexate, mycophenolate mofetil (MMF), and hydroxyurea; as well as the newer BRMs, specifically adalimumab, alefacept, etanercept, infliximab, and ustekinumab.

Acitretin In the 1980s, etretinate became the first oral retinoid, or vitamin A acid derivative, available for the treatment of psoriasis. It has since been replaced by acitretin, its active metabolite.

Retinoids may be less effective than methotrexate or cyclosporine when used as monotherapy. Currently, acitretin is more commonly used in combination with topical calcipotriol or phototherapy.[23,26] Its efficacy appears to be dose dependent,[26] but low-dose acitretin (25 mg/day) is safer and better tolerated than higher-dose (50 mg/day) therapy.[23]

Common adverse effects of acitretin include hypertriglyceridemia and mucocutaneous adverse effects such as dryness of the eyes, nasal and oral mucosa, chapped lips, cheilitis, epistaxis, xerosis, brittle nails, and burning or sticky skin.[23,26] Less commonly, "retinoid dermatitis" may occur. Periungual pyogenic granulomas are sometimes seen after long-term use of acitretin.[26] Rarely, skeletal abnormalities—such as disseminated idiopathic skeletal hyperostosis (DISH) syndrome—may occur.[23]

All retinoids are teratogenic and are pregnancy category X, including topical retinoids. Acitretin should not be used for women of childbearing age unless they are able and willing to use effective birth control not only for the duration of acitretin therapy but also for 3 years after discontinuing the agent.[23,26] Men receiving acitretin should not donate blood for a similar time period.

Ethanol should be avoided during therapy and for 2 months after drug discontinuation since it causes the transesterification of acitretin to etretinate, which has a much longer elimination half-life.

Cyclosporine Cyclosporine is a systemic calcineurin inhibitor. The original formulation, marketed as Sandimmune, was first approved as a posttransplant immunosuppressant to prevent organ rejection. The more bioavailable microemulsion formulation, Neoral, was approved by the FDA in 1997 for the treatment of psoriasis and rheumatoid arthritis.[29]

Cyclosporine is efficacious for both inducing remission and maintenance therapy for patients with moderate to severe plaque psoriasis. It is also effective in treating pustular, erythrodermic, and nail psoriasis.[29]

In comparative randomized controlled trials, cyclosporine was significantly more effective than etretinate[52] and similar or slightly better in efficacy than methotrexate.[23,29,53] After inducing remission, maintenance therapy using low doses (1.25 mg/kg/day to 3.0 mg/kg/day) may prevent relapse.[29] The dose should always be titrated to the lowest effective dose for maintenance. In one placebo-controlled study, the relapse rate was 42% for patients on 3.0 mg/kg/d versus 84% for patients on placebo.[54]

For patients discontinuing cyclosporine, a gradual taper of 1 mg/kg/day each week may prolong the time before relapse, as compared with abrupt discontinuation.[26,29] Abrupt discontinuation resulted in a dramatic rebound of psoriasis in a few cases.[23] Because more than half of patients discontinuing cyclosporine will relapse within 4 months, patients should be provided with appropriate alternative treatments shortly before or after discontinuing cyclosporine therapy.[29]

Adverse effects of cyclosporine include cumulative renal toxicity, hypertension, and hypertriglyceridemia. The latter two are particularly significant for patients with prior elevation of diastolic blood pressure or triglycerides.[23] Hypertriglyceridemia can occur in up to 15% of patients with psoriasis who are treated with cyclosporine, although this effect is generally reversible upon cessation of therapy.[26]

The risk of SCC and other nonmelanoma skin cancers increases with duration of treatment[23] and with prior PUVA treatments.[26] Thus, although continuous therapy for up to 2 years may be efficacious,[29] it should be used only in a subset of patients[23] in whom renal function is monitored with annual determinations of glomerular filtration rate (GFR) and monthly measurements of blood pressure and creatinine clearance, with more frequent measurements during the initial 6 weeks of treatment.[23]

Baseline blood pressure, serum creatinine, serum urea nitrogen, triglycerides, complete blood count, uric acid, potassium and magnesium should be obtained before initiating therapy, every 2 weeks for the first 12 weeks of therapy, and monitored monthly thereafter during therapy.[23,29] Age-appropriate malignancy screens should also be done, and patients should be seen for dental examinations at least yearly because of the risk of gingival hyperplasia.[29]

The 2009 Canadian Guidelines recommended that cyclosporine be normally reserved for intermittent use in periods up to 12 weeks for most patients with psoriasis,[23] although other recommendations

are for periods of 1 year or up to 2 years.[29] Risk of toxicity increases with treatment duration.

As a CYP3A4 substrate, cyclosporine has significant drug interactions. Serum concentration monitoring is not routinely needed for patients with psoriasis because doses used are lower than in transplant recipients, although monitoring may be advisable for patients taking interacting drugs.

Drugs that can increase cyclosporine concentrations include calcium channel blockers (verapamil, diltiazem, and nicardipine), amiodarone, thiazide diuretics, macrolide antibiotics, allopurinol, oral contraceptives, ezetimibe, selective serotonin reuptake inhibitors (fluoxetine, sertraline), fluoroquinolones (ciprofloxacin, norfloxacin), antifungals (ketoconazole, itraconazole, fluconazole, voriconazole), and cimetidine.[29] Grapefruit juice will also increase cyclosporine concentrations.

Drugs that can reduce cyclosporine concentrations include anticonvulsants (carbamazepine, oxcarbazepine, phenobarbital, phenytoin, valproic acid), efavirenz, and St. John's wort.[29]

Conversely, cyclosporine may also affect the drug levels of some drugs. Concurrent use of potentially interacting drugs should be avoided when possible.

Methotrexate For decades, methotrexate has been the mainstay of systemic therapy for patients with moderate to severe psoriasis. It has direct antiinflammatory benefits due to its effects on T-cell gene expression and also has cytostatic effects.[23] It is more efficacious than acitretin and similar or slightly less efficacious than cyclosporine.[23,31]

Although it also has a significant adverse effects profile, methotrexate is generally considered a safer alternative than cyclosporine unless there are preexisting contraindications such as liver disease. In some head-to-head clinical studies more patients dropped out of the cyclosporine treatment arms due to adverse effects.[26,31] While BRMs are undoubtedly more efficacious, they are much more costly, and some insurance companies require an inadequate response or intolerance to methotrexate (the gold standard) as a prerequisite for approving their use.[31] In a recent placebo-controlled comparative study with adalimumab, the efficacy of methotrexate was 36% versus 80% for adalimumab and 19% for placebo.[55] Adalimumab also provided a more rapid response; however, the duration of remission is unclear. Methotrexate can be used continuously for years or decades with sustained benefits.[23]

Methotrexate inhibits folate biosynthesis; and the use of folate supplementation during prolonged methotrexate therapy as seen in dermatology remains controversial (see Clinical Controversy box).

CLINICAL CONTROVERSY: FOLATE SUPPLEMENTATION FOR METHOTREXATE THERAPY

Although some experts recommend folate supplementation for all patients receiving methotrexate for psoriasis, others add folate only when patient issues occur, such as gastrointestinal adverse effects or early bone marrow toxicity (as manifested by an increased mean corpuscular volume) that can be caused by megaloblastic anemia.[26,31] Lack of folate supplementation has also been listed as a risk factor for hepatotoxicity from methotrexate use.[31] One small placebo-controlled study suggested that folate supplementation may result in a slight decrease in efficacy of treatment;[92] but the study methodology has been questioned.[26,31]

The most significant adverse effect is cumulative liver toxicity; and total lifetime dose of methotrexate must be monitored. Traditionally, patients received a pretreatment liver biopsy and subsequent biopsies when a cumulative dose of 1.5 g is reached. Currently, it is recognized that pretreatment liver biopsies may not be practical or appropriate in all cases[23,31] and that baseline liver biopsies only be considered for patients with a history of significant liver disease.[31] It has also been recommended that a baseline liver biopsy be delayed for 2 to 6 months so that medication efficacy and tolerability can first be established[31] (i.e., intention to continue with methotrexate use). Risk factors for hepatotoxicity from methotrexate include the following: a history of or current alcohol consumption, persistent abnormal liver chemistry studies, history of liver disease including chronic hepatitis B or C, family history of inheritable liver disease, history of significant exposure to hepatotoxic drugs or chemicals, diabetes mellitus, obesity, and hyperlipidemia.[26,31] For patients without preexisting risk factors for hepatotoxicity, it is recognized that they would likely have a low risk of fibrosis and would not require a baseline liver biopsy; furthermore, consideration can be made to continue methotrexate treatment for these patients without biopsies at all, to perform a liver biopsy after 3.5 to 4.0 g total cumulative dose, or to switch therapy to an alternate drug at that point.[26,31]

Other adverse effects include significant nausea, pulmonary toxicity, pancytopenia, acute myelosuppression, megaloblastic anemia, and a small but significant increase in lymphoma.[23] Although rare, pancytopenia can occur anytime with the use of low-dose weekly methotrexate and even after single doses of methotrexate.[26] Methotrexate is an abortifacient and is teratogenic (pregnancy category X) and should not be used in pregnancy. After methotrexate therapy is discontinued, it is recommended that men continue an effective birth control for 3 months (since one cycle of spermatogenesis is 74 days), and women should be on effective birth control for at least one ovulatory cycle.[23,26]

Significant drug interactions include serum albumin binding interactions with salicylates, phenytoin, sulfonamides/trimethoprim, ciprofloxacin, and thiazide diuretics, potentially increasing toxicity. Drugs that can reduce methotrexate renal elimination (such as acidic drugs, including salicylates or vitamin C) will also increase serum methotrexate levels and hence increase toxicity. In addition, drugs with hepatotoxic potential may pose an additive risk with methotrexate use.[26]

Systemic Therapy with Biologic Response Modifiers

⑩ Some BRMs have proven efficacy for psoriasis; however, there are differences among these agents, including mechanism of action, duration of remission, and adverse-effect profile. In general, due to their immunomodulatory effects, there is an increased risk of infection with most of these agents. The use of live or live-attenuated vaccines during therapy is generally contraindicated. Currently, BRMs are often considered for patients with moderate to severe psoriasis when other systemic agents are inadequate or relatively contraindicated. BRMs are sometimes recommended for first-line therapy, alongside conventional systemic agents, for patients with moderate to severe psoriasis; however, in practice, drug access due to cost considerations may be a limiting factor. BRMs may be appropriate if comorbidities exist. For example, BRMs such as etanercept would be an appropriate treatment option for patients with both plaque psoriasis and active PsA. BRMs currently available for treatment of psoriasis include adalimumab, alefacept, etanercept, infliximab, and ustekinumab.[56]

Tumor Necrosis Factor-α Inhibitors. Dysregulation of TNF-α production has been associated with various inflammatory

conditions, including rheumatoid arthritis, inflammatory bowel disease, ankylosing spondylitis, PsA, and psoriasis.[57] Elevated TNF-α levels are seen in both the affected skin and serum of patients with psoriasis; and these elevated levels have a significant correlation with psoriasis severity.[28] The biologic agents etanercept, adalimumab, and infliximab are TNF-α inhibitors. They offer the prospect of more rapid disease control than is commonly seen with the other BRMs.[23] After successful control of psoriasis, TNF-α levels are reduced to normal.[28]

There are safety concerns common to TNF-α inhibitors, mainly from observations made through their use in rheumatoid arthritis and inflammatory bowel disease. One concern is an increased risk of infections, most commonly upper respiratory tract infections, and less commonly serious infections including sepsis, new-onset or reactivation tuberculosis, and opportunistic infections such as histoplasmosis, cryptococcosis, aspergillosis, candidiasis, and pneumocystis.[23,28] There have been reports of serious pulmonary and disseminated histoplasmosis, coccidioidomycosis, and blastomycosis infections,[60,61] sometimes with fatal outcomes when these infections were not consistently recognized and promptly treated in the patients taking TNF-α inhibitors.[60]

A second concern is the development or worsening of autoimmune diseases such as peripheral and central demyelinating disorders including multiple sclerosis and drug-induced lupus-like syndromes.[23,28,61] A third concern is the potential increased risk of malignancies such as lymphoma,[23,28,61] melanoma, and nonmelanoma skin cancer.[28] A fourth concern is the potential for other cutaneous adverse effects including vasculitis, granulomatous reactions, cutaneous infections, psoriasiform eruptions, and infusion or injection site reactions.[57] Flares of pustular psoriasis have been reported primarily for patients undergoing treatment for nondermatologic conditions such as rheumatoid arthritis.[23] There is also a concern about congestive heart failure (CHF), although this has now become controversial due to conflicting studies demonstrating both worsening and improvement.[28]

The current recommendation from the American Academy of Dermatology is that TNF-α inhibitors be avoided in patients with severe CHF (New York Heart Association class III or IV), and those with milder CHF should have their TNF-α inhibitors withdrawn at the onset of new symptoms or worsening of preexisting CHF.[28]

Although the above are safety concerns common to etanercept, adalimumab, and infliximab, their safety profiles are not identical. For example, the risk for tuberculosis (TB) is lowest with etanercept and highest with infliximab.[23] They are pregnancy category B and safe to use in pregnancy.[28]

Adalimumab is a human monoclonal antibody that provides rapid and efficacious control of psoriasis.[28] In a double-blind, randomized controlled and open-label extension study of patients with moderate to severe psoriasis, significant improvement was often seen within 1 week of therapy, complete or nearly complete clearance was seen forn some patients, and clinical benefits were maintained for at least 1 year with continuous therapy for most patients.[23,59] As discussed in the methotrexate section, in a recent head-to-head study adalimumab was significantly more efficacious than methotrexate.[55] Adalimumab is given as 80 mg subcutaneously in the first week, then 40 mg the following week, and thereafter 40 mg every other week continuously.[23,28] More frequent dosing has been explored.[23]

Etanercept was one of the earliest BRMs available on the market for use in inflammatory diseases. It has demonstrated efficacy for rheumatoid arthritis. It was approved for use in PsA in the United States in June 2002 and approved in 2004 for use in moderate to severe psoriasis.[61] It is also approved for treatment of juvenile rheumatoid arthritis and ankylosing spondylitis. Thus, as opposed to some of the other BRMs approved for psoriasis, etanercept has been extensively used in rheumatology both for adults and children.

The dosing of etanercept in psoriasis differs from its other indications, reflective of the dosing regimens found to be effective for psoriasis in clinical trials. Etanercept is used continuously, given as 50 mg subcutaneously twice weekly for the first 12 weeks, followed by 25 mg twice weekly[23] or 50 mg once weekly.[28,61] Significant improvement was seen in about 50% of patients in clinical trials by week 12 and more than 50% of participants by week 24; with continuing therapy, weaker responders continued to improve for up to 1 year.[23,26,62] Continuing therapy using 50 mg twice weekly regimens are being explored and may provide greater benefit.[23] Etanercept was efficacious in children and adolescents (aged 4 to 17 years) with plaque psoriasis dosed at 0.8 mg/kg (maximum 50 mg) once weekly.[63]

Infliximab also received approval for rheumatologic diseases before psoriasis and was on the market before adalimumab. Unlike etanercept or adalimumab, infliximab is a chimeric antibody with both murine and human components; thus, antibodies to the drug can develop, resulting in infusion reactions.[28] Regular therapy rather than intermittent dosing on an as-needed basis may minimize this occurrence.[28] The standard dosing regimen is three intravenous infusions of 5 mg/kg given over a 6-week induction period, followed by regular infusions every 8 weeks.[23]

Clinical response is seen rapidly. In a randomized controlled phase III trial, 80% of patients responded by week 10 (after 3 doses of infliximab); however, the response dropped to about 50% by week 50.[64,65] Rare reports of serious adverse events, including fatal cases of hepatosplenic T-cell lymphomas, have been associated with infliximab use.[28] Other rare instances of cholecystitis and autoimmune hepatitis, which may be a class effect for TNF-α inhibitors, have also been reported.[23]

Alefacept Alefacept was the first BRM to receive approval for the treatment of psoriasis, in January 2003 in the United States and in October 2004 in Canada. Over the years, it has accumulated an extensive and reassuring safety record, with no evidence of increased incidence of infections, cancers, or any other serious adverse events beyond background levels. The exception is that CD4 T lymphocytes can be depleted, and CD4 cell counts must be monitored.[23,66]

In comparison with other BRMs, alefacept monotherapy provides only limited control of psoriasis, and as discussed later, it is often explored in combination regimens to enhance response.[23] However, even with monotherapy, long periods of near complete remission can be seen occasionally.[23]

Dosing is intended to be intermittent. Alefacept is given for a 12-week course, then repeated only when the loss of control becomes unacceptable (up to two more courses per year).[23] Maximal response was generally seen by 6 to 8 weeks in responders, and currently there is no measure to predict which patients will respond.[28]

Ustekinumab Ustekinumab is an IL-12/23 monoclonal antibody and the newest BRM, having been approved for the treatment of psoriasis in adults 18 years or older with moderate to severe plaque psoriasis in Canada in December 2008 and in the United States in September 2009.[67] It selectively targets IL-12 and IL-23, two cytokines that play a role in the pathogenesis of psoriasis.

Two large randomized placebo-controlled trials demonstrated clinical efficacy of ustekinumab, with approximately 70% of patients achieving 75% skin clearance after two doses and maintaining the response for 1 year with continued treatment.[67]

Dosing is 45 mg for patients weighing 100 kg (220 lb) or less, and 90 mg for those of higher weights. Ustekinumab is administered subcutaneously at weeks 0 and 4, then every 12 weeks as maintenance therapy.

Common adverse effects include upper respiratory infections, headache, and tiredness. Serious adverse effects include those seen with other BRMs, including serious tubercular, fungal, viral infections, and cancers. In addition, a reversible posterior leukoencephalopathy syndrome (RPLS) has been reported.[67]

Combination Therapies

Combination therapies may be beneficial in the management of plaque psoriasis: generally to either enhance efficacy or minimize toxicity. As shown in Figures 107–1 and 107–2, combinations can include two topical agents, a topical agents plus phototherapy, a systemic agent plus topical therapy, a systemic agent plus phototherapy, two systemic agents used in rotation, or a systemic agent and a BRM. Rotational therapy is not commonly used in practice, and the use of a BRM added to a systemic agent is still under investigation.

The combination of a topical corticosteroid and a topical vitamin D3 analogue is particularly useful. This was shown in several studies to be efficacious and safe, with less skin irritation than monotherapy with either agent, and the combination product containing calcipotriol and betamethasone dipropionate ointment has demonstrated efficacy in randomized controlled trials for patients with relatively severe psoriasis.[23,27] The combination may also be steroid sparing.[27]

The combination of retinoids with phototherapy has also been shown to increase efficacy. Since retinoids may be photosensitizing and increase the risk of burning after UV exposure, doses of phototherapy should be reduced to minimize adverse effects. A randomized controlled trial with tazarotene and broadband UVB not only showed significant enhancement of UVB efficacy but also reduced the number of UVB treatment sessions needed for response.[25,27,68] The combination of acitretin and broadband UVB reduced the number of needed treatments, compared with UVB alone.[23,69] Acitretin with NB-UVB (RE-UVB) was highly effective for patients with difficult-to-control psoriasis.[26,70] The combination of acitretin and PUVA (RE-PUVA) also showed greater efficacy than monotherapy with either agent.[25,71] RE-PUVA can be used to achieve clearance with up to a twofold reduction in total UV exposure.[23] Phototherapy has also been used with other topical agents, such as UVB with coal tar (Goeckerman regimen)[49] to increase treatment response, since coal tar is also photosensitizing.

BRMs used in combination with other therapies are being explored. Some beneficial combinations have been found. Alefacept and NB-UVB in combination significantly reduced the number of UVB treatments needed with clearance seen in 43% of patients within 12 weeks.[23,72] Infliximab given concurrently with immunosuppressive agents such as methotrexate or azathioprine may result in a lower incidence of infusion reactions to infliximab.[28]

Alternative Drug Treatments

Mycophenolate Mofetil MMF is a systemic agent occasionally used for patients with resistant cases of moderate to severe psoriasis.[23] This is currently not an approved indication in either Canada or the United States.

A few reports and small studies are available describing the efficacy of MMF when used as monotherapy or adjuvant therapy.[73] In addition, one small study evaluated the switch for eight patients with severe psoriasis from cyclosporine to MMF after a washout period of 2 to 4 weeks. On cyclosporine, seven of these patients had deteriorating renal function and hypertension, and one experienced loss of efficacy.[74] After the switch to MMF, there was significant loss of psoriasis control in five of the eight patients but also significant improvement in renal function for six patients.[73,74]

Conversely, another small study evaluated the sequential use of MMF followed by cyclosporine in eight patients with moderate to severe psoriasis.[75] There was significant improvement with MMF in all patients, and all patients further improved when switched to cyclosporine.[75]

MMF has some uncommon but significant adverse effects, including increased incidence of opportunistic infections such as cytomegalovirus, cryptococcosis, candidiasis, and *Pneumocystis jirovecii*.[73] Cases of progressive multifocal leukoencephalopathy have also been reported.[73] There may be an associated risk of malignancy.[76]

Hydroxyurea Hydroxyurea is an antimetabolite usually used for cancer treatments, but it has also been used in the systemic treatment of psoriasis for more than 30 years.[23,26] It is still occasionally tried for patients with recalcitrant severe psoriasis, although BRMs may be a better option for these patients.

Hydroxyurea has been compared with methotrexate for patients with moderate to severe psoriasis.[77] Weekly regimens showed greater efficacy for methotrexate with a faster clearance rate, although hydroxyurea was also efficacious. The authors concluded that weekly doses of hydroxyurea may be an alternative to methotrexate for patients experiencing intolerable methotrexate side effects or have reached the recommended cumulative dose.[77]

Adverse effects of hydroxyurea include significant bone marrow suppression, lesional erythema, localized tenderness, and reversible hyperpigmentation.[23,77]

Complementary and Alternative Medicines. The use of complementary and alternative medicines (CAM) among patients with psoriasis is common, with a prevalence of 43% to 69% in various studies.[78] Most of these patients use herbs, special diets, or dietary supplements in conjunction with their usual antipsoriatic medications and not as replacements. Most patients do not discuss CAM use with their physicians.[78]

A 2009 systematic review of randomized controlled trials found that, although there is a large body of literature on CAM use in psoriasis, the quality of most studies was relatively low.[78] CAM agents and interventions with documented clinical efficacy in psoriasis include *Mahonia aquifolium*, fish oil, climatotherapy (Dead Sea salts), and stress reduction techniques.

Mahonia aquafolium (Oregon grape, Mountain grape, or barberry but *not* European barberry) is an evergreen native to southern British Columbia, western Oregon, and northern Idaho. The rhizome and root contain berberine as the primary active constituent. Berberine is an alkaloid that inhibits keratinocyte growth and reduces keratinocyte proliferation, and it also has antibacterial and antifungal activities. In at least two clinical trials *Mahonia aquifolium* was efficacious in reducing disease severity: In one randomized placebo-controlled study a *Mahonia aquifolium* 10% preparation applied topically twice daily resulted in a significant improvement in the PASI score and the Quality of Life Index (QLI), compared with placebo.[79] Adverse effects in clinical trials included rash, burning sensation, redness, and itching.

Fish oil contains two important long-chain polyunsaturated fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). EPA and DHA are omega-3 fatty acids. They act as substrates competing with arachidonic acid for cyclooxygenase and lipoxygenase, thus reducing the production of proinflammatory molecules in psoriatic plaques.[78] Several randomized, placebo-controlled, and/or comparative trials for patients with psoriasis have demonstrated efficacy of fish oils. One study comparing EPA plus etretinate to etretinate monotherapy found significantly greater efficacy with the combination of EPA plus etretinate.[80]

Climatotherapy refers to the practice of traveling to the Dead Sea and sunbathing and/or bathing in the sea—the beneficial effects are likely from the high salinity of the sea and UV rays.[78] Several studies have demonstrated efficacy, including two studies using saline spa baths. One study used highly concentrated (25% to 27%) saline spa

baths plus UVB compared with UVB alone, and the other used low concentrated (4.5% to 12%) saline spa bath plus UVB again compared with UVB alone. In both studies the clinical response was significantly better with the saline spa bath plus UVB combination.[78,81,82]

Stress-reduction techniques have inconsistently shown some benefit. One randomized study demonstrated that both meditation or meditation and imagery were efficacious as adjunctive treatments for patients with scalp psoriasis.[83] A second randomized study for patients with psoriasis receiving either UVB or PUVA therapy showed that the addition of a mindfulness-based stress-reduction audiotape played during light treatments reduced response times for patients receiving UVB but not PUVA therapy.[84] This confirmed the belief that psychological stress plays a role in psoriasis. More recently, in a case-control study of risk factors during the year before the onset of psoriasis, stressful life events were found to be significant.[85,86]

Special Populations

Psoriasis in Children Pediatric psoriasis is more often attributable to direct precipitating factors such as skin trauma, infections, drugs, or stress.[23,87] Compared with adults, plaque lesions in children are often smaller, thinner, and less scaly, which can make diagnosis more difficult. Face and flexures are more commonly involved than for adults. Psoriatic diaper rash can occur up to age 2. PsA is rare.[23]

Topical treatment is the standard of care for children with psoriasis, with topical corticosteroids often the treatment of first choice.[23] Other useful pharmacologic therapies include calcipotriol and anthralin; calcipotriol with or without topical corticosteroids has also been recommended as treatment of first choice[88] because it produces minimal adverse effects.[23] Since children's skin is thinner and better hydrated than that of adults, they are at higher risk of drug absorption leading to systemic adverse effects. The lowest potency corticosteroid that provides control should be used, and it should be tapered as the lesions improve. If long-term calcipotriol is used, monitoring of ionized calcium is recommended because of the risk of hypercalcemia.[23]

Systemic therapies are reserved for children with severe and recalcitrant psoriasis.[23,88] Methotrexate can provide near to complete clearance[88] and has been safely used to control severe childhood psoriatic episodes and then withdrawn as lesions improve.[23] Regular monitoring for liver and blood toxicity is required.[23] The BRM etanercept was recently studied in a randomized, placebo-controlled trial of 211 children and adolescents (4 to 17 years) with moderate to severe plaque psoriasis. It significantly reduced disease severity; however, four serious adverse events occurred (ovarian cyst requiring removal, gastroenteritis, gastroenteritis-associated dehydration, and left basilar pneumonia).[89] Etanercept has been studied in children with polyarticular juvenile rheumatoid arthritis without new safety concerns emerging.[23]

Phototherapy should be used with caution, especially for younger children, because of long-term carcinogenic risks and phototoxicities. For older children and adolescents with severe, extensive, or treatment-resistant disease, UVB may be a treatment option.[23]

Psoriasis in Pregnancy Hormonal changes in pregnancy can improve symptoms for patients with plaque psoriasis. In one study, 55% of patients showed improvements during pregnancy.[23,90] For patients with more than 10% BSA involvement who reported improvement, lesions decreased by more than 80% during pregnancy.[90] This appeared to correlate with high estrogen but not progesterone levels.[90] Thus, some pregnant women may require minimal treatment for their psoriasis.

Some antipsoriatic drugs have significant teratogenic risks, placing them in pregnancy category X. Thus, women of childbearing potential must use effective birth control during therapy, and may need to continue effective contraception after discontinuing therapy for a period of time, as discussed in detail throughout this chapter. In addition, drugs listed as pregnancy category C may carry known teratogenic risks in animal studies or have limited available data for use in pregnancy.

UVB has been considered the safest treatment for extensive psoriasis during pregnancy. It is recommended for patients with widespread disease not controlled by topical agents. One problem with this therapy is an increased potential for reactivation of herpes simplex, which may be transmitted to the infant at delivery.[23]

For more detailed information about antipsoriatic drugs in pregnancy, a systematic, drug-by-drug review of case reports and case-control studies is available.[91] The 2009 Canadian Guidelines for the Management of Plaque Psoriasis provides a drug-by-drug summary of recommendations for topical agents, phototherapy, and systemic agents in pregnancy.[23]

Psoriasis in the Elderly. Age-related changes in organ function/drug clearance and greater drug sensitivity increase the risk of adverse drug events for elderly patients with psoriasis.

Methotrexate is hepatotoxic and should be used with caution in the elderly. Cyclosporine has nephrotoxic potential and may also increase blood pressure. Both drugs have significant drug interactions, and polypharmacy, common in older patients, makes management of interactions challenging.

In addition, older patients may have preexisting comorbidities, such as hyperlipidemia and metabolic syndrome, and this may further limit drug use. Topical psoriasis treatments are often prescribed for elderly patients as first-line therapy[23]; however, even with topicals, adverse effects—including systemic ones—can occur with greater frequency in these patients.[23]

Psoriasis in Patients with a History of Solid Tumors. As discussed throughout this chapter, many antipsoriatic therapies carry significant cancer risks. PUVA, systemic therapies such as cyclosporine, and some BRMs are associated with increased risks of oncologic disorders.

A systematic review of the risk of malignancy associated with therapies for moderate to severe psoriasis confirmed the following[76]: PUVA is associated with an increased risk of cutaneous SCC and malignant melanoma; UVB is a much safer therapeutic modality than PUVA; cyclosporine increases risks of lymphoma, internal malignancies, and skin cancers; methotrexate may be associated with increased melanoma and Epstein–Barr virus–associated lymphomas; MMF may be associated with lymphoproliferative disorders; and the malignancy risk may be increased for biologic agents, especially the TNF-α inhibitors.[76]

The 2009 Canadian guidelines recommend that TNF-α inhibitors be used with caution for patients with a history of malignancy or existing malignancies, and the T-cell modulator alefacept is contraindicated for these patients.[23]

PHARMACOECONOMIC CONSIDERATIONS

⑩ The wide gap in costs of agents for psoriasis makes economics and availability of insurance or other coverage important considerations in formulating a therapeutic plan.

Currently, the expensive BRMs are often considered for patients with moderate to severe psoriasis when less expensive systemic agents are inadequate or relatively contraindicated. BRMs have also been recommended as first-line therapy, alongside conventional systemic agents, for patients with moderate to severe psoriasis; however, in practice, drug access secondary to cost considerations can limit use. These agents may be needed early, though, for some patients with comorbidities.

A recent pharmacoeconomic analysis of BRMs in the treatment of psoriasis suggests that the cost-to-benefit ratio for BRMs may be favorable.[58]

CONCLUSIONS

Psoriasis is a life-long illness with no known cure. Significant comorbidities may coexist. Treatment should be patient specific, with consideration given to disease severity, patient risk factors, age, and comorbidities. Newer treatment modalities, including numerous BRMs, are now part of the armamentarium available in the management of this disease.

ABBREVIATIONS

BRM: biologic response modifier

BSA: body surface area

CYP3A4: cytochrome P450 isoenzyme 3A4

DISH: disseminated (or diffuse) idiopathic skeletal hyperostosis

DLQI: Dermatology Life Quality Index

HLA: major histocompatibility complex antigen

HPA: hypothalamic–pituitary–adrenal

IL: Interleukin

MMF: mycophenolate mofetil

NSAIDS: nonsteroidal antiinflammatory drugs

NB-UVB: narrowband ultraviolet B (311 nm ultraviolet B light)

PASI: Psoriasis Area and Severity Index

PGA: Physician's Global Assessment

PML: progressive multifocal leukoencephalopathy

PUVA: psoralens plus ultraviolet A

QLI: Quality of Life Index

RE-PUVA: retinoid plus PUVA (as combination therapy)

RE-UVB: retinoid plus NB-UVB (as combination therapy)

RPLS: reversible posterior leukoencephalopathy syndrome

SCAT: short-contact anthralin therapy

SCC: squamous cell carcinoma

SF-36: Short Form Health Survey

SPF: sun protection factor

TNF-α: Tumor necrosis factor-α

UVA: ultraviolet A (315 to 400 nm ultraviolet A light)

UVB: ultraviolet B, or broadband UVB (28 to 315 nm ultraviolet B light)

CHAPTER 108 Atopic Dermatitis

REBECCA M. LAW AND PO GIN KWA

KEY CONCEPTS

1. Atopic dermatitis is a chronic skin disorder involving inflammation associated with intense pruritus, a hallmark symptom. Management of atopic dermatitis must always include appropriate management of the associated pruritus.
2. Atopic dermatitis is associated with other atopic diseases such as asthma and allergic rhinitis in the same patient or family. The three conditions are known as the *atopic triad*.
3. The prevalence of atopic dermatitis appears to have increased two- to threefold in many developed and developing countries during the past three decades. Recent data indicate age and country or regional differences, with some countries showing no change or even a decrease. Rural areas appear to have lower prevalence rates.
4. There are genetic and environmental factors in the pathogenesis and pathophysiologic manifestations of atopic dermatitis. The inheritance pattern is not straightforward. More than one gene may be involved in the disease, with the filaggrin gene (*FLG*) being a key player.
5. Atopic dermatitis often presents in infants and young children. The clinical presentation differs somewhat depending on the age of the patient.
6. Secondary bacterial skin infections are common in patients with atopic dermatitis and must be promptly treated.
7. Management of atopic dermatitis must always include appropriate nonpharmacologic management of any controllable environmental factors, such as avoidance of identified triggers. These may include aeroallergens (e.g., mold, grass, pollen), foods (e.g., peanuts, eggs, tomatoes), chemicals (e.g., detergents, soaps), clothing material (e.g., wool, polyester), temperature (e.g., excessive heat), and humidity (e.g., low humidity).
8. Nonpharmacologic management of atopic dermatitis entails managing the symptoms associated with pruritus and encouraging appropriate skin care habits such as proper bathing techniques and the copious use of moisturizers, which is a standard of care.
9. Topical corticosteroids are the drugs of first choice for atopic dermatitis.
10. Topical calcineurin inhibitors (tacrolimus and pimecrolimus) are alternate treatment options for adults and children over the age of 2 years.
11. This chronic illness has substantial socioeconomic impact. The cost may be magnified by undertreatment.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Atopic dermatitis (AD) is a common skin disease. It is often referred to as *eczema*, which is a general term for several types of skin inflammation. Atopic dermatitis is the most common type of eczema (Table 108–1).[1] It is a chronic skin disorder involving inflammation with pruritus as the hallmark symptom/presentation. This disorder is often the prelude to atopic diathesis, which includes asthma and other allergic diseases.

2 This form of dermatitis is commonly associated with other atopic disorders, such as allergic rhinitis and asthma. Atopic dermatitis, allergic rhinoconjunctivitis, and asthma are known collectively as the *atopic triad*.[2] Atopic dermatitis has also been defined as the cutaneous manifestation of atopy.[2]

The disease can have periods of exacerbation, or flare ups, followed by periods of remission. These flare ups may be disruptive to the patient's quality of life and may affect the entire family. Disease flare-ups are difficult to manage and may be complicated by

TABLE 108-1 Types of Eczema (Dermatitis)[1]

- **Allergic contact eczema (allergic contact dermatitis):** A red, itchy, weepy reaction where the skin has come into contact with a substance that the immune system recognizes as foreign, such as poison ivy or certain preservatives in creams and lotions.
- **Atopic dermatitis (or irritant contact dermatitis):** A chronic skin disease characterized by itchy, inflamed skin.
- **Contact eczema:** A localized reaction that includes redness, itching, and burning where the skin has come into contact with an allergen (an allergy-causing substance) or with an irritant such as an acid, cleaning agent, or other chemical.
- **Dyshidrotic eczema:** Irritation of the skin on the palms of hands and soles of the feet characterized by clear, deep blisters that itch and burn.
- **Neurodermatitis:** Scaly patches of the skin on the head, lower legs, wrists, or forearms caused by a localized itch (such as an insect bite) that become intensely irritated when scratched.
- **Nummular eczema:** Coin-shaped patches of irritated skin—most common on the arms, back, buttocks, and lower legs—that may be crusted, scaling, and extremely itchy.
- **Seborrheic eczema:** Yellowish, oily, scaly patches of skin on the scalp, face, and occasionally other parts of the body.
- **Stasis dermatitis:** A skin irritation on the lower legs, generally related to circulatory problems.

secondary infections. About one half (estimate up to 65%) of cases in children first manifest before age 1 year [1–4]; these cases are termed *early-onset atopic dermatitis*.[5] About 85% of patients develop symptoms before age 5.[1]

Of the children with atopic dermatitis diagnosed before age 1 year, approximately 40% to 60% will have the same skin condition continuing into their adulthood.[1,3]

Onset after age 30 is much less common and is often caused by exposure to harsh or wet conditions[1] such as repeated skin trauma or exposure to harsh chemicals. In adults, the prevalence is believed to be 1% to 3%, with an overall lifetime prevalence of about 7%.[1]

EPIDEMIOLOGY

3 The prevalence of atopic dermatitis is generally said to have increased two- to threefold in developed and developing countries during the past three decades.[5] Currently in developed countries, an estimated 15% to 30% of children and 2% to 10% of adults are affected.[5,6] The prevalence appears to be increasing worldwide, since earlier prevalence rates were estimated at 10% to 15% in children.[4]

3 A 2008 study has found both age and country differences in prevalence rates.[7] This international study included 187,943 children aged 6 to 7 years from 64 centers in 35 countries and 302,159 adolescents aged 13 to 14 years from 105 centers in 55 countries. For children aged 6 to 7 years, most countries showed an increase of 2 standard deviations (SDs) in mean annual prevalence over a 5- to 10-year period. In contrast, for adolescents aged 13 to 14 years, the trends differ from country to country. Large increases in prevalence were seen in developing countries (e.g., Mexico, Chile, Kenya, and Algeria, and seven countries in Southeast Asia). But in other countries with formerly very high prevalences, the mean annual prevalence in eczema symptoms has either leveled off or decreased. Most of the largest decreases (SD ≥2) in prevalence were reported from developed countries in northwest Europe, (e.g., the United Kingdom, Ireland, Sweden, Germany) and New Zealand.[7]

There were no differences according to the sex of the study participant, or with gross national income at a country level.[7] This is consistent with other reports that atopic dermatitis affects males and females at about the same rate.[1] This international study demonstrating different trends according to age group is partly corroborated by a study from the United Kingdom suggesting that the prevalence of allergic disorders (eczema and hay fever) might have leveled off or decreased over the past 10 years in those aged 12 years or older, but increased among younger children.[8]

There appears to be a lower prevalence of atopic dermatitis in rural areas when compared with urban areas, suggesting a link to the *hygiene hypothesis*, which postulates that the absence of early childhood exposure to infectious agents increases susceptibility to allergic diseases.[9–11] In contrast, children attending day care centers before 3 months of age have less atopy and asthma in later childhood,[11,12] and areas with diffuse and chronic helminth infestations have a low prevalence of allergic diseases.[11] In addition, a recent European birth cohort study involving 1,133 newborns showed that children born to farm families had a lower prevalence of sensitization to seasonal inhaled allergens such as grass pollen.[13] Maternal exposure during pregnancy (i.e., prenatal exposure) to animal sheds correlated with the lower prevalence rate in the farm children.[12] However, there were no differences in prevalence related to inhaled perennial allergens.

ETIOLOGY

4 Atopic dermatitis is a complex genetic disease that arises from gene–gene and gene–environment interactions. There are two major groups of genes involved. First, there are the genes encoding for epidermal or other epithelial structural proteins. Second, there are genes encoding for the major elements of the immune system.[5]

The inheritance pattern is not straightforward. More than one gene is likely involved in the disease. There is an increased risk for a child to have atopic dermatitis if there is a family history of other atopic diseases, such as hay fever or asthma. The risk is significantly higher if both parents have an atopic disease.[1] Studies of identical twins show that a person whose identical twin has atopic dermatitis is seven times more likely to have atopic dermatitis than someone in the general population.[1] And a person whose fraternal twin has atopic dermatitis is three times more likely to have atopic dermatitis than someone in the general population.[1]

Thus, genetic predispositions to developing atopic dermatitis exist. Specifically, there are several possible genes on the chromosomes 3q21, 1q21, 16q, 17q25, 20p, and 3p26. Of these chromosomes, 1q21 has the highest linkage region. This region has a family of epithelium-related genes called the epidermal differentiation complex.[5] One of these genes, the filaggrin gene (*FLG*), on chromosome 1q21.3, was initially identified as the gene involved in ichthyosis vulgaris, and several mutations of this gene were subsequently identified in European and Japanese patients with atopic dermatitis.[14] *FLG* encodes for a key protein in epidermal differentiation. Mutations or deficiency of *FLG* results in an abnormality in permeability barrier function.[15]

Epidermal barrier dysfunction is a prerequisite for the penetration of high-molecular-weight allergens in pollens, house dust mite products, microbes, and food.[5] In mice studies, this barrier abnormality alters thresholds for irritant and acute allergic contact dermatitis, and *FLG* deficiency predisposes to the development of an atopic dermatitis-like dermatosis.[15] In humans, two common *FLG* variants (*R501X* and *2282de14*) with an estimated combined allele frequency of about 6% have been identified in individuals of European descent.[16] Eighteen other less common variants have also been identified in Europeans, with an additional 17 mutations restricted to individuals of Asian descent.[16] Each of these variants leads to nonsense mutations which either prevent or severely diminish the production of filaggrin in the epidermis.[16] Mutations of *FLG* seem to occur mainly in early-onset atopic dermatitis patients and may be associated with the development of asthma in patients with atopic dermatitis.[5,16] However, *FLG* mutations are identified in only 30% of European patients with atopic dermatitis; implying that other genetic mutations affecting other epidermal structures may be important (e.g., changes in the cornified envelope proteins involucrin and loricrin, or lipid composition).[5]

There are other genes encoding for the immune system that may be associated with atopic dermatitis, especially those found on chromosome 5q31-33.[5] These genes code for cytokines that regulate IgE synthesis. Cytokines are produced mainly by type 1 and type 2 helper T cells. Type 1 helper T cells (Th1) produce cytokines which suppress IgE production (e.g., interferon-γ and interleukin 12 [IL-12]).[5] Type 2 helper T cells (Th2) produce cytokines which increase IgE production (e.g., IL-5 and IL-13).[5,17] In patients with atopic dermatitis, there is an imbalance between Th1 and Th2 immune responses. These patients are genetically predisposed to Th2 predominance, seen as increased Th2 cell activity.[2,5,17] Increased Th2 activity causes the release of IL-3, IL-4, IL-5, IL-10, and IL-13, resulting in blood eosinophilia, increased serum IgE, and increased growth and devel-

opment of mast cells.[2,5,17,18] In addition, these cytokines affect the maturation of B cells and cause a genomic rearrangement in these cells that favors isotype class switching from IgM to IgE.[5]

In summary, recent data suggests that *FLG* deficiency alone can provoke a barrier abnormality in the epidermis and predispose to the development of dermatitis by enhancing allergen absorption through the skin.[19] Furthermore, there appears to be complex relationships, including genetic and nongenetic risk factors, that modify an individual's susceptibility to allergic disease.[20] Complex genetic factors contribute to the increased susceptibility to atopic dermatitis (*FLG* mutations and gene–gene interactions). These, along with environmental factors (gene–environment interactions), result in the pathophysiologic changes and clinical presentations associated with atopic dermatitis.

PATHOPHYSIOLOGY

The initial mechanisms that trigger inflammatory changes in the skin in patients with atopic dermatitis are unknown. Neuropeptides, irritation, or pruritus-induced scratching may be causing the release of proinflammatory cytokines from keratinocytes. Alternatively, allergens in the epidermal barrier or in food may cause T-cell mediated but IgE-independent reactions. Allergen-specific IgE is not a prerequisite.[5]

Skin barrier dysfunction plays a critical role in the development of atopic dermatitis,[21,22] and loss of function mutations in the skin structural protein *filaggrin* is a major risk factor.[22] Other factors may include a deficiency of skin barrier proteins, increased peptidase activity, lack of certain protease inhibitors, and lipid abnormalities.[22] There must be epidermal barrier dysfunction for high-molecular-weight allergens in pollens, house dust mite particles, microbes, and foods to penetrate the skin barrier. Atopic skin has reduced antimicrobial peptides (AMPs). AMPs are normally produced by keratinocytes, sebocytes, and mast cells and they form a chemical shield on the surface of the skin. Reduced AMPs result in a diminished antimicrobial barrier, which correlates with increased susceptibility to infections and superinfections seen in these patients.[23]

Upon penetration of the epidermal barrier, allergens are met by dendritic cells (DCs). DCs are antigen-presenting cells populating the skin, respiratory tract, and mucosa of the GI tract (i.e., at the front line of pathogen entry).[24] DCs then enhance Th2 polarization, resulting in increased production of IgE. Keratinocytes in the skin of patients with atopic dermatitis also produce high levels of an interleukin-7–like protein, which again drives dendritic cells to enhance Th2 polarization. Epidermal dendritic cells in patients with atopic dermatitis bear IgE and express its high-affinity receptor (FcεRI).[25–27] Serum IgE is often elevated in patients with atopic dermatitis,[1,18] especially during an exacerbation.

However, upon initial presentation, patients with early-onset atopic dermatitis generally do not have increased IgE levels (i.e., there is no detectable IgE-mediated allergic sensitization). IgE-mediated allergic sensitization may occur several weeks or months after the initial atopic dermatitis lesions appear. Although in some children—mostly girls—this sensitization never occurs.[5]

PREDISPOSING FACTORS

Several factors can predispose patients to development of atopic dermatitis. These include climate, infection, genetics, environmental aeroallergens, and food.

Hot and extremely cold climates are both poorly tolerated by patients with this condition. Dry weather, common in the winter, causes increased skin dryness. Hot weather causes increased sweating, resulting in pruritus.

Patients with atopic dermatitis are commonly colonized by *Staphylococcus aureus* bacteria. Clinical infections with *S aureus* frequently cause flare-ups of atopic dermatitis.

As discussed previously, genetics plays a role in atopic dermatitis. Family history of atopic dermatitis is common.

Exposure to environmental aeroallergens is another risk factor. Dust mites, pollens, molds, cigarette smoke, and dander from animal hair or skin may worsen the symptoms of atopic dermatitis.[1,18]

The role of food as antigens in the pathogenesis of atopic dermatitis is controversial. Small amounts of environmental foods (low-dose exposure from foods on tabletops, hands, dust) may penetrate the skin barrier and be taken up by Langerhans cells, leading to Th2 responses and IgE production.[28] However, early high-dose oral food consumption induces oral tolerance. The timing and balance of cutaneous and oral exposure determines whether a child will have allergy or tolerance. [28] Increased serum IgE antibodies to a particular food is consistent with a food allergy.[1] Eczema may frequently be a manifestation of food allergy,[28] and patients with atopic dermatitis have a higher prevalence of food allergy than those in the general population.[1]

This is consistent with the known epidermal barrier dysfunction in atopic dermatitis, allowing for increased low-level skin permeability to allergenic foods. Certain foods may trigger acute reactions, including urticaria and anaphylaxis. The most commonly reported allergenic foods are eggs, milk, peanuts, wheat, soy, tree nuts, shellfish, and fish.[1] Individual food allergies, such as peanut allergy, have increased in prevalence in the past decade;[28,29] new food allergies may also be increasing in prevalence, particularly kiwi allergy[28,30] and sesame seed allergy.[28,31] Consistent with the oral tolerance concept, early results from recent studies using sublingual and oral immunotherapy to specific food allergens (e.g., milk or peanut) appear to indicate that it may be possible to induce oral tolerance, and that it may be possible to desensitize children to some allergenic foods. Currently, these treatment protocols have only been done in highly supervised research settings and with small numbers of patients.[32]

CLINICAL PRESENTATION

Diagnosis of atopic dermatitis is generally based on clinical presentation (Table 108–2)[1] There is no objective diagnostic test for the clinical confirmation of atopic dermatitis.[1,33] Filaggrin gene mutations may be associated with persistent and more severe atopic dermatitis as well as early-onset cases.[22]

TABLE 108-2 Skin Features Associated with Atopic Dermatitis[1]

- **Atopic pleat (Dennie–Morgan fold)**: An extra fold of skin that develops under the eye.
- **Cheilitis**: Inflammation of the skin on and around the lips.
- **Hyperlinear palms**: Increased number of skin creases on the palms.
- **Hyperpigmented eyelids**: Eyelids that have become darker in color from inflammation or hay fever.
- **Ichthyosis**: Dry, rectangular scales on the skin.
- **Keratosis pilaris**: Small, rough bumps, generally on the face, upper arms, and thighs.
- **Lichenification**: Thick, leathery skin resulting from constant scratching and rubbing.
- **Papules**: Small raised bumps that may open when scratched and become crusty and infected.
- **Urticaria**: Hives (red, raised bumps) that may occur after exposure to an allergen, at the beginning of flares, or after exercise or a hot bath.

5 The clinical presentation of atopic dermatitis differs somewhat depending on the age of the patient. In infancy, the earliest onset of atopic dermatitis usually occurs between 2 and 6 months of age, and especially between the sixth and twelfth weeks of life.[1,2] It has been reported that 75% of cases have their onset within the first six months.[2] A more conservative estimate is that at least 65% of patients develop symptoms within the first year of life, and at least 85% will have developed symptoms before the age of 5.[1] The initial presentation in infancy is an erythematous, papular skin rash that may first appear on the cheeks and chin as a patchy facial rash[1,2] and that can progress to red, scaling, oozing skin.[1] The rash shows a centrifugal distribution affecting the malar region of the cheeks, forehead, scalp, chin, and behind the ears while sparing the central areas (i.e., the nose and paranasal creases).[2] Lesions occur in the flexor surfaces, such as antecubital and popliteal fossae. Over the next few weeks and as the infant becomes more mobile and begins crawling, the lesions spread to the extensors of the lower legs, and eventually the entire body may be involved, with sparing of the diaper area and the nose.[1] These lesions are associated with uncontrollable itchiness, and the infant will become irritable and may try to rub his or her face to relieve the itch. Scratching may occur quite early, and infants with atopic dermatitis may scratch themselves continuously, mainly when they are undressed or during sleep.[2] Excessive rubbing or scratching may result in excoriation and development of secondary infections.

In childhood, the skin often appears dry, flaky, rough, cracked, and may bleed due to scratching. With repeated scratching and rubbing the skin becomes lichenified. Lichenification, usually localized to the flexural folds of the extremities,[33] is very characteristic of childhood atopic dermatitis in older children and adults.[33,34] Lichenification signifies repeated rubbing of the skin and is seen mostly over the folds, bony protuberances, and forehead.[34] Excoriations and crusting are also commonly seen, along with secondary infections. Sometimes increased folds are seen underneath the eyes (so called Dennie–Morgan folds).[34] Lesions are still most commonly seen in the flexor surfaces of the body, particularly the flexural creases of the antecubital and popliteal fossae.[34]

Sleep disturbances also occur. One study reported that there are both brief and longer awakenings associated with scratching episodes that affect sleep efficiency in school-age children with atopic dermatitis.[35]

In adulthood, lesions are more diffuse with underlying erythema. The face is commonly involved and may be dry and scaly. Lichenification may again be seen. A brown macular ring around the neck, representing a localized deposit of amyloid, is typical but not always present.[34]

Although no objective diagnostic test confirms presence of atopic dermatitis,[1] some signs, symptoms, and other factors are commonly used in its diagnosis. These include pruritus, early age of onset, eczematous skin lesions that vary with age, chronic and relapsing courses, dry and flaky skin, IgE reactivity, family or personal history of asthma or hay fever, or other atopic diseases (Table 108–3).[18] In addition, allergy skin testing may be helpful in identifying factors that trigger flares of atopic dermatitis.[1] Negative results may help rule out certain substances as triggers; however, positive results may be unrelated to disease activity, and false positives are common.[1]

1 Pruritus is a quintessential feature of atopic dermatitis, and a diagnosis cannot be made if there is no history of itching.[1–4] Atopic dermatitis has been called the itch that, when scratched, erupts.[2] Scratching or rubbing itchy, atopic skin characterizes this type of eczema.[2] Scratching and rubbing further irritates the skin, increases inflammation, and exacerbates itchiness.[3] Atopic skin can itch during sleep. This nighttime itching is a problem for many children with the disease, since there is no conscious control of scratching during sleep.[1,18,35]

TABLE 108-3 Major and Minor Signs and Symptoms of Atopic Dermatitis[1]

Major indicators
- Pruritus (intense itching)
- Characteristic rash in locations typical of the disease
- Chronic or repeatedly occurring symptoms
- Personal or family history of atopic disorders (eczema, hay fever, asthma)

Selected minor indicators
- Early age of onset
- Dry skin that may also have patchy scales or rough bumps
- Increased serum IgE
- Numerous skin creases on the palms
- Hand or foot involvement
- Inflammation around the lips
- Nipple eczema
- Susceptibility to skin infection
- Positive allergy skin tests

Pruritus can be triggered by a variety of factors. The most common triggers of itch have been reported as heat and perspiration (96%), wool (91%), emotional stress (81%), certain foods (49%), alcohol (44%), upper respiratory infections (36%), and house dust mites (>35%).[36]

Once pruritus occurs, the surrounding normally nonpruritic skin area (whether inflamed or noninflamed) may be very sensitive and react to light stimuli and begin itching (allokinesis). Allokinesis is typical of atopic dermatitis.[18,36] As a result of allokinesis, patients with atopic dermatitis may experience pruritic attacks when their skin is touched accidentally by mechanical factors such as clothing,[18] especially wool products.[36]

Elevated serum IgE may be seen, consistent with the genetically predetermined dominance of Th2 cytokines causing increased IgE. In addition, increased serum IgE antibodies to a particular food, consistent with a food allergy,[3] is common in patients with atopic dermatitis. The radioallergosorbent test (RAST) is an allergen-specific IgE antibody test used to screen for allergy to a specific substance or substances. In some cases the RAST test may be used to monitor immunotherapy or to see if a child has outgrown a specific allergy. Positive (elevated) RAST usually indicates an allergy to a suspected or known allergen. However, the level of IgE may not correlate with the severity of an allergic reaction, and the IgE level may remain elevated for years after an allergy has been outgrown.[18]

A clinically useful set of criteria for the diagnosis of atopic dermatitis is as follows: atopy, pruritus, eczema, and altered vascular reactivity.[18,36]

COMPLICATIONS

6 Patients with atopic dermatitis are prone to skin infections. Atopic skin is drier and the stratum corneum has weakened protective abilities; combined with the abnormal skin barrier function and immune defense, there is an increased risk of secondary bacterial skin infections with staphylococci or streptococci, and viral infections such as herpes simplex or even fungal infections.[1] Constant scratching to relieve pruritus may cause excoriations, further compromising the integrity of the skin barrier. *S aureus* is a common cause of secondary bacterial infections in atopic dermatitis. Binding of *S aureus* is enhanced by skin inflammation as seen in atopic dermatitis.[21] Many patients with atopic dermatitis are colonized with *S aureus* and may have exacerbations after skin

infections of this organism.[21] Secondary bacterial infections may present as yellowish crusty lesions and should be promptly treated. Oral (systemic) antibiotics are generally more effective than topical treatment.[1,21]

Patients with atopic dermatitis are also more prone to disseminated infections with herpes simplex or vaccinia virus.[21] Severe viral infections such as eczema herpeticum or eczema vaccinatum might be linked to the severity of atopy.[21] Smallpox vaccination is contraindicated in patients with atopic dermatitis.[21]

TREATMENT

In treating patients with atopic dermatitis, clinicians generally have the following clinical goals in mind:

1. Provide symptomatic relief—control the itching
2. Control the atopic dermatitis
3. Identify and, when possible, eliminate triggers and environmental aeroallergens
4. Identify and minimize predisposing factors for exacerbations including any stressors
5. Prevent future exacerbations
6. Provide any social and psychological support needed for the patient, family, and caregivers
7. Minimize or prevent adverse events from medications and other treatment modalities
8. Treat to cure any secondary skin infections, if present

7 Both nonpharmacologic and pharmacologic therapies are important in managing the signs and symptoms of atopic dermatitis. Nonpharmacologic strategies include identifying and minimizing or eliminating preventable risk factors such as known triggers and allergens, as well as appropriate skin care.

Treatment guidelines and protocols for atopic dermatitis are available. These are listed in Table 108–4.

NONPHARMACOLOGIC THERAPY

8 Nonpharmacologic approaches to the treatment of infants and children with atopic dermatitis include the following[1]:

- Give lukewarm baths.
- Apply lubricant immediately after bathing (moisturizers are a standard of care).[10]
- Keep child's fingernails filed short.
- Select clothing made of soft cotton fabrics.
- Consider using sedating antihistamines to reduce scratching at night.
- Keep the child cool; avoid situations in which overheating occurs.
- Learn to recognize skin infections and seek treatment promptly.
- Attempt to distract the child with activities to keep him or her from scratching.
- Identify and remove irritants and allergens.

Hydration is crucial, and adequate skin hydration is a fundamental part of managing atopic dermatitis.[3] Transepidermal water loss is greater in atopic skin than in normal skin. Thus, any measures to improve skin moisturization, such as liberal use of moisturizers, would be beneficial. Moisturizers are a standard of care and may be steroid-sparing.[10] They are useful for both prevention and maintenance therapy.[10] They can be categorized based on their specific effects on the skin:

- *Occlusives:* These agents provide an oily layer on the skin surface to slow transepidermal water loss, increasing the moisture content of the stratum corneum. These are the best moisturizers for patients with atopic dermatitis.[3]
- *Humectants:* In the stratum corneum, these agents increase the water-holding capacity. However, they are not useful in patients with atopic dermatitis because they have a stinging effect on open skin.[3]
- *Emollients:* These agents smooth out the surface of the skin by filling the spaces with droplets of oil. These are the least effective moisturizers.[3]

The humidity in the home should be kept at or above 50% and the room temperature kept on the cool side.[18]

Appropriate skin care is crucial in preventing flare-ups.[1] A daily skin care routine should include the following[18]:

- Using scent-free moisturizers liberally as needed each day.
- Bathing in lukewarm water (never hot) for about 5 minutes once[3,37] or twice[3] daily. Adding a capful of emulsifying oil may help the body retain moisture; baths are better than showers. If showering, mild liquid cleansers are preferred over soaps.[3]
- The skin should be air dried or lightly towel dried (pat to dry, avoid rubbing or brisk drying).[1,37,38]
- Scent-free moisturizer should then be applied while the skin is still moist or slightly damp (within 3 minutes of towel drying).[3,38] Some fragrance-free moisturizers include Aveeno

Baby Soothing Relief Moisture Cream, Cetaphil, Neutrogena Hand Cream, and Vanicream products. Lotions may be used on the scalp and other hairy areas and for mild dryness on the face, trunk, and limbs; creams are more occlusive than lotions; ointments are the most occlusive and can be used for drier, thicker, or more scaly areas.[3] Occlusive moisturizers are best.[3]

- Using nonsoap skin cleansers[1] may cause less skin irritation. Lipid- and fragrance-free skin cleansers may be particularly advantageous (e.g., Cetaphil Gentle Skin Cleanser, Free and Clear Liquid Cleanser, Spectro Derm Cleanser). Aquanil, Dove, Neutrogena, and pHisoderm sensitive skin products have also been recommended as low-irritant products, and some are lipid free.
- Avoiding alcohol-containing topical products including lotions, swabs, and wipes, as they may be drying.
- Clothing should be double-rinsed. Mild detergents should be used to wash clothing, with no bleach or fabric softener.[3]

PHARMACOLOGIC THERAPY

Topical Corticosteroids

8 *Topical corticosteroids* are the standard of care to which other treatments are compared.[10] They remain the drug treatment of choice for atopic dermatitis. However, despite their extensive use, supporting data are limited regarding optimal corticosteroid concentrations, duration and frequency of therapy, and quantity of application.[10] The use of long-term intermittent application of topical corticosteroids was beneficial and safe in two randomized controlled studies;[10] however, independent studies of other formulations are needed.[10]

To maximize the antiinflammatory benefit and minimize adverse effects, the choice of corticosteroid should be matched with the severity and site of disease.[3] Low-potency corticosteroids, such as hydrocortisone 1%, are suitable for the face, and medium-potency corticosteroids, such as betamethasone valerate 0.1%, may be used for the body.[3] For longer-duration maintenance therapy, low-potency corticosteroids are recommended.[33] Mid-strength and high-potency corticosteroids should be used for short-term management of exacerbations.[33] Ultra-high and high-potency corticosteroids, such as betamethasone dipropionate 0.05% or clobetasone propionate 0.05%, are typically reserved for short-term treatment of lichenified areas in adults.[39] After the lesions have cleared or significantly improved, a lower-potency steroid should be used for maintenance when necessary.[39] Potent fluorinated corticosteroids should be avoided not only on the face, but also the genitalia and the intertriginous areas, and in young infants.[33] (For a corticosteroid potency comparison chart, see Table 107–2 or the National Psoriasis Foundation Website at *http://www.psoriasis.org/netcommunity/sublearn03_mild_potency*.)

It is also important to remember that altering the local environment through hydration and/or occlusion as well as changing the vehicle[39] may alter the absorption and effectiveness of the topical corticosteroid.[10] Some vehicles are better suited for certain body areas,[39] such as a lotion for the scalp and hairy areas. Foams may be more cosmetically pleasing to some patients, as they easily disappear into the skin. The surface area of the skin involved and the skin thickness also play a role.[33] In addition, tachyphylaxis is a clinical concern, but there is no experimental documentation.[10]

Adverse effects of topical corticosteroids may be systemic in nature, and they are directly related to the steroid potency, duration of use, and other factors as discussed above. Local adverse effects include striae and skin atrophy, perioral dermatitis, acne, rosacea, telangiectasias, and allergic contact dermatitis (often related to the vehicle).[33,40] The potential for systemic adverse effects is related to the potency of the topical corticosteroid, the site of application, the occlusiveness of the preparation, the percentage of body surface area covered, and the duration of use.[33] Potential systemic effects include hypothalamic–pituitary–adrenal (HPA) axis suppression, infections, hyperglycemia, cataracts, glaucoma, and growth retardation (in children).[1,3,9,18,40] However, growth retardation may also be related to the chronicity of the illness rather than to corticosteroid use or dietary factors.[3] Although less likely, systemic adverse effects can occur with low-potency topical corticosteroids. For example, a recent phase II study of a mild-potency corticosteroid (desonide 0.05% foam) in children and adolescents 3 months to 17 years showed that 4% (3 of 75) of patients experienced mild reversible HPA-axis suppression after a 4-week treatment period.[41]

When topical steroid therapy has failed for efficacy or safety reasons, numerous agents and interventions can be used as alternative or add-on therapy in patients with atopic dermatitis.

Topical Calcineurin Inhibitors

9 Topical immunomodulators such as the calcineurin inhibitors tacrolimus ointment (Protopic) and pimecrolimus cream (Elidel) have been shown to reduce the extent, severity, and symptoms of atopic dermatitis in adults and children.[10] Tacrolimus has been reported to inhibit the activation of key cells involved in atopic dermatitis, including T cells, dendritic cells, mast cells, and keratinocytes.[33] Pimecrolimus acts similarly to tacrolimus, inhibiting T-cell proliferation, preventing gene transcription of Th1 and Th2 cytokines, and reducing mediator release from mast cells and basophils.[33] However, pimecrolimus has more favorable lipophilic characteristics and, in animal studies, appears to preferentially distribute to the skin as opposed to the systemic circulation.[33,42] Both tacrolimus ointment and pimecrolimus cream are approved for atopic dermatitis in adults and children older than age 2.[3,10,42] Although clinical trials conducted in younger infants (e.g., 2–23 months old) also showed significant efficacy without appreciable adverse effects, use in children younger than age 2 is not FDA approved.[43] Tacrolimus 0.03% ointment is approved for moderate to severe atopic dermatitis for ages 2 and above, with the 0.1% ointment limited to ages 16 and above; pimecrolimus 1% cream is approved for mild to moderate atopic dermatitis for ages 2 and above.[43]

Due to continuing concerns regarding a possible risk of cancer with tacrolimus and pimecrolimus,[43] both drugs are recommended for use as second-line treatments in atopic dermatitis.[9,10,37] They may be appropriate in patients with corticosteroid-related adverse effects, patients with large body-surface areas of disease, patients unresponsive to corticosteroids, or when treatment with corticosteroids is inadvisable.[3] Children and adults with a weakened or compromised immune system should not be treated with these agents. Unlike topical corticosteroids, calcineurin inhibitors can be used on all body locations for prolonged periods,[3] although episodic use is recommended.[37] Skin atrophy does not occur.[33]

The most common adverse effect of topical calcineurin inhibitors is transient discomfort (burning sensation) at the application site.[3] There is a potential for local skin carcinogenesis as seen in animal studies, or for systemic effects if high blood levels are reached (for example, increased susceptibility to infections due to immunosuppressive effects).[43] Since there is a possible risk of cutaneous malignancy,[3,37] sun protection is recommended.[3,18,37,43] Patients should be encouraged to apply a high sun protection factor broad-spectrum sunblock daily to all exposed skin (e.g., SPF 30 or higher); and this counseling should especially be

emphasized for those patients with the highest risk of developing skin cancer, including patients with red hair and/or Fitzpatrick skin types I and II, and patients receiving phototherapy or using tanning beds.[43]

Topical calcineurin inhibitors are very effective in relieving the associated pruritus. Pimecrolimus therapy has been shown in a controlled long-term (6-month) study in adults with atopic dermatitis to significantly reduce pruritus within 48 hours (48.3% reduction versus 15.9% reduction in the placebo group; $P < 0.001$).[3,44]

Phototherapy

Phototherapy is effective for atopic dermatitis and is recommended[10] especially when the disease is not controlled by tacrolimus or pimecrolimus ointment. Phototherapy may be steroid sparing, allowing for the use of lower-potency topical corticosteroids, or even eliminating the need for maintenance corticosteroids in some cases. Phototherapy may also help prevent secondary bacterial skin infections, commonly seen in patients with atopic dermatitis. However, in a few patients, phototherapy may worsen the atopic dermatitis; it is not recommended in patients whose disease flares up when exposed to sunlight. Relapse following cessation of therapy frequently occurs.[10]

Phototherapy may consist of either ultraviolet light therapy alone, or ultraviolet light therapy alongside drug or topical ointment (commonly called photochemotherapy). Psoralens plus ultraviolet A light (PUVA) is one type of photochemotherapy. The photosensitizer (psoralens) is administered either orally or in a bath immediately prior to UVA therapy. Topical ointments (such as crude coal tar) may also be used concomitantly with ultraviolet light therapy (e.g., Crude coal tar + UVB).

Ultraviolet lamps include UVA (315–400 nm), UVA1 (340–400 nm), broadband UVB (280–315 nm), and narrowband UVB (311 nm). Phototherapies used for atopic dermatitis have included PUVA, high- or medium-dose UVA1, wideband UVB, and narrowband UVB.[10,45] There is weaker evidence supporting the use of PUVA in atopic dermatitis.[45] Narrowband UVB is more effective than broadband UVB therapy. Broadband UVB may not effectively treat the scalp and skin fold areas. Medium-dose UVA1 is very effective for patients with an acute exacerbation of severe atopic dermatitis; however, the effect may be relatively short-lived and symptoms recurred within 3 months of stopping therapy in one adult study.[45,46] A recent adult study comparing medium-dose UVA1 and narrowband UVB found no difference in efficacy; however, the sample size was quite small (N = 13), and the follow-up period was confounded by the use of topical corticosteroids.[47] On-going clinical trials are comparing UVA1 and UVB light therapy for atopic dermatitis and other inflammatory skin conditions.

Patients need to wear eye protection during UV therapy to prevent damage to the retina. Short-term adverse effects include erythema, skin pain, skin burning or sunburn, pruritus, and pigmentation.[33] Long-term adverse effects include premature aging of the skin (photoaging) and skin cancer.[33,45] For example, PUVA has been associated with squamous cell carcinoma and possibly melanoma, which may occur years after PUVA therapy has ceased.[45]

Coal Tar

Although tar preparations had been widely used for atopic dermatitis and are recommended as alternative topical therapy,[10] few randomized controlled studies support their efficacy.[33] Their anti-inflammatory properties are not well characterized, and part of the improvement with the agent may be the result of a placebo effect, which can be significant in atopic dermatitis.[33]

Coal tar products are also staining and malodorous, although newer products may be more cosmetically acceptable. They are not recommended on acutely inflamed skin, since this may result in additional skin irritation.[33]

The use of coal tar in pregnancy has not been studied. Few data are available about tar excretion into breast milk; in addition, safety in children has not been established.[48] Adverse effects include tar folliculitis, acneiform eruptions, irritant dermatitis, burning, stinging, photosensitivity, and a risk of tar intoxication if used extensively in a young child.[48] Although animal studies showed that tar components can be converted to carcinogenic/mutagenic entities, there is inconclusive epidemiologic evidence supporting the claim that human use of topical tar preparations in dermatology leads to skin cancer.[48]

SYSTEMIC THERAPIES

Systemic therapies for the treatment of atopic dermatitis are generally not well studied or approved by FDA. Small case series or open studies are available for some agents, but few well-conducted randomized controlled trials exist. Agents described in published papers have included systemic corticosteroids, cyclosporine, interferon-γ, azathioprine, methotrexate, mycophenolate mofetil, intravenous immunoglobulin (IVIG), and more recently biologic response modifiers.

Systemic corticosteroids, such as oral prednisone, rarely may be required as a short term treatment for severe, recalcitrant, chronic atopic dermatitis.[33] While not routinely recommended,[37] systemic corticosteroids can provide rapid relief of severe refractory disease during transition to other therapies.[45] The dosage of the drug must be tapered during discontinuance to minimize a rebound flare-up. Intensified skin care, particularly with topical corticosteroids and moisturizers, is also important during the taper to minimize a rebound flare-up.[33]

Cyclosporine is considered effective for severe atopic dermatitis,[10] but its usefulness is limited by significant side effects, including hypertension and nephrotoxicity. There is also the potential for significant drug–drug and drug–food (e.g., grapefruit juice) interactions. It should be reserved for short-term use in adults or children with severe refractory disease.[45] Maximal benefit is usually seen after about 2 weeks of use and relapse may occur quickly after cessation of therapy.[45]

Recombinant interferon-γ may be effective in a subset of patients with atopic dermatitis.[10] Two randomized placebo-controlled trials in patients with severe atopic dermatitis demonstrated significant improvement in symptoms.[49,50] Short-term adverse effects, such as headache, myalgias, and chills, occurred in substantial proportions of study patients. Transient liver transaminase elevations and granulocytopenia have also occurred.[51] Long-term therapy (up to 24 months) did not appear to be associated with significant adverse events.[33] Some recommend that a higher dose of this agent be used initially followed by a lower dosage during maintenance therapy.[45]

Azathioprine,[33,52] *methotrexate,*[53] *mycophenolate mofetil,*[33] and *IVIG* have shown efficacy in small case series or open-label studies primarily in adults with recalcitrant atopic dermatitis. They are rarely used. Oral methotrexate, with a long history of pediatric use for various inflammatory conditions, appeared to be effective in a case series of children (aged 2–16 years) with severe atopic dermatitis.[53]

Biologic response modifiers, unlike for psoriasis, are currently not approved for atopic dermatitis. The safety and efficacy of various biologic response modifiers in patients with atopic dermatitis have been studied,[51] mostly in case reports, small case series, or open-label studies with a limited number of patients. Theoretically, using protein-based therapies is inherently risky in a patient population more prone to developing IgE sensitization to protein antigens

than the general population. Type 1 immediate hypersensitivity reactions such as anaphylaxis could result, and patients with severe disease are potentially the patients at greatest risk of anaphylaxis. None has been reported in the published literature, which detail 261 patients with atopic dermatitis treated with various biologics,[51] but these numbers are too small to generalize their findings to larger numbers of people or specific populations.

More specifically, the TNF-α inhibitors infliximab and etanercept appeared effective in a few patients but not others, and adverse events have included infusion reactions with flushing and dyspnea, urticaria, and recurrent skin infections of methicillin-resistant *S aureus*. Similarly, omalizumab, rituximab, and alefacept have been shown in a few case reports and small case series to be somewhat effective.

Additional research is needed to determine the therapeutic potential and safety of biologics in patients with atopic dermatitis.[51]

Complementary and Alternative Therapies

Traditional Chinese herbal therapy has been studied in placebo-controlled trials and appeared to provide temporary benefit for patients with severe atopic dermatitis. However, the effectiveness may wear off despite continued treatment, and long-term toxicity is unknown.[10,33,54,55]

Mycobacterium vaccae (killed) injected intradermally was found to be effective in reducing the severity of skin disease in a placebo-controlled trial in children with moderate to severe atopic dermatitis.[56] This suggests that down-regulation of the Th2 response in atopic dermatitis may potentially be beneficial.[33]

Probiotics of various types have been studied in placebo-controlled trials with mixed results. One study group reported that prenatal and postnatal exposure for 6 months to *Lactobacillus rhamnosus GG* halved the frequency of atopic dermatitis at 2, 4 and 7 years but had no effect on atopic sensitization. Other study groups also administered lactobacilli, including *L rhamnosus GG*, but with mixed results. One study showed that *L acidophilus* supplementation actually increased the risk of atopic sensitization.

A recent placebo-controlled study comparing *Bifidobacterium lactis* and *L rhamnosus HN001* found that *L rhamnosus HN001* may be effective in preventing the development of atopic dermatitis in high-risk infants.[57]

More research is needed about the role of probiotics in treating patients with atopic dermatitis.

Immunotherapy using allergen-specific desensitization techniques in controlled settings for patients with atopic dermatitis may also be beneficial, and much research is ongoing. Double-blind controlled studies have not shown consistent efficacy.

More research is also needed to adequately assess the role of homeopathy, hypnotherapy, acupuncture, massage therapy, and biofeedback therapy in the treatment of atopic dermatitis.[10]

PHARMACOECONOMICS AND OTHER CONSIDERATIONS

11 Atopic dermatitis may have significant implications not only for the patients themselves, but also their families and caregivers.

In 2006, an international study of 2,002 patients and caregivers from 8 countries addressed the effect of atopic dermatitis on the lives of patients and society.[58] This European study found that, on average, patients experienced 9 flares per year, with those having severe disease experiencing more flares and taking significantly longer to clear. The flares were associated with disturbed sleep, and 86% of patients avoided at least one type of everyday activity. Schoolwork performance and productivity were negatively affected. Patients missed an average of 2.5 days of school or work per year, and an analysis of adult patient performance at work and occupational absence showed that the social cost of lost productivity could amount to more than 2 billion euros per year across the European Union. There were also emotional consequences; half of the patients experienced depression or unhappiness about their condition, and one third reported that atopic dermatitis had eroded their self-confidence. In addition, concern about adverse effects from topical corticosteroid treatments resulted in poor adherence to therapy. On average, patients endured the symptoms of atopic dermatitis without initiating specific treatment 47% of the time they had an exacerbation. About one half of the respondents were concerned about using topical corticosteroids, and 58% restricted them to particular sites, 39% used them less frequently or for shorter time periods than prescribed, and 66% used them as a last resort. The study concluded that atopic dermatitis is "an undertreated disease that has a significant, yet mostly avoidable, negative effect on patients, their caregivers, and society."[58]

Thus, health care professionals play an integral role in providing patient and caregiver education about this disease and specific treatment plans. The importance of adequate and appropriate education for the patient, family, and caregivers about atopic dermatitis and its management cannot be overemphasized. Patients should be involved in their own care.

CLINICAL CONTROVERSY

Animal studies showed that coal tar components can be converted to carcinogenic/mutagenic entities, and tar keratoses (small nodules that develop from cutaneous tar exposure) have the potential to regress, fall off, or develop into a squamous cell carcinoma. However, there is inconclusive epidemiologic evidence supporting the claim that human use of topical tar preparations in dermatology leads to skin or internal cancers such as bladder cancer or lymphoma.[48]

CLINICAL CONTROVERSY

With topical calcineurin inhibitors, there is a potential for local skin carcinogenesis as seen in animal and in vitro studies. In addition, pigmented melanocytic lesions have been seen in treated areas, raising concern about melanoma.[43] FDA has a black-box warning for both tacrolimus ointment and pimecrolimus cream about their potential cancer risk, but no causal relationship has been proven between use of a topical calcineurin inhibitor and the development of lymphoma or nonmelanoma skin cancer.[43]

EVALUATION OF THERAPEUTIC OUTCOMES

Successful management of atopic dermatitis should include not only clearance of skin lesions, which may take days to weeks depending on the severity of disease, but also control of the itch, minimizing or eliminating triggers, monitoring the patient to minimize or prevent adverse events from medications or other treatment modalities, and providing adequate social and psychological support for the patient, family, and caregivers. The ultimate goal is to provide enough control of this chronic disease that future exacerbations are prevented, thus ensuring that the patient's quality of life is minimally affected by atopic dermatitis.

CONCLUSIONS

Atopic dermatitis is a chronic skin condition that generally presents at an early age, It affects the patient, family, and caregivers. Nonpharmacologic management strategies are important in treatment; these include appropriate skin care, hydration, avoidance of triggers, and psychosocial support. Pharmacologic treatment emphasizes topical corticosteroids as the standard of care. Patient and caregiver education about atopic dermatitis and treatment strategies is critical to minimize nonadherence. Successful outcomes result when patients and caregivers are partners with health care professionals in the management of this chronic disease.

SECTION 15
HEMATOLOGIC DISORDERS

CHAPTER 109

Anemias

KRISTEN COOK, BEATA A. INECK, AND WILLIAM L. LYONS

KEY CONCEPTS

1. Anemia is a group of diseases characterized by a decrease in either hemoglobin (Hb) or the volume of red blood cells (RBCs), which results in decreased oxygen-carrying capacity of the blood. Anemia is defined by the World Health Organization as Hb <13g/dL (<130 g/L; <8.07 mmol/L) in men and <12g/dL (<120 g/L; <7.45 mmol/L) in women.
2. Acute onset anemias are most likely to present with tachycardia, lightheadedness, and dyspnea. Chronic anemia often presents with weakness, fatigue, headache, vertigo, and pallor.
3. Iron-deficiency anemia (IDA) is characterized by decreased levels of ferritin (most sensitive marker) and serum iron, as well as decreased transferrin saturation. Hb and hematocrit decrease later. RBC morphology includes hypochromia and microcytosis. Most patients are adequately treated with oral ferrous sulfate therapy, although parenteral iron therapy is necessary in selected patient populations.
4. Vitamin B_{12} deficiency, a macrocytic anemia, can be due to inadequate intake, malabsorption syndromes, and inadequate utilization. Anemia caused by lack of intrinsic factor, resulting in decreased vitamin B_{12} absorption, is called *pernicious anemia*. Neurologic symptoms can be present and can become irreversible if the vitamin B_{12} deficiency is not treated promptly. Oral or parenteral therapy can be used for replacement.
5. Folic acid deficiency, a macrocytic anemia, results from inadequate intake, decreased absorption, and increased folate requirements. Treatment consists of oral administration of folic acid, even for patients with absorption problems. Adequate folic acid intake is essential in women of childbearing age to decrease the risk of neural tube defects in their children.
6. Anemia of chronic disease is a diagnosis of exclusion. It results from chronic inflammation, infection, or malignancy and can occur as early as 1 to 2 months after the onset of the disease. The serum iron level usually is decreased, but in contrast to IDA, the serum ferritin concentration is normal or increased. Treatment is aimed at correcting the underlying pathology.
7. Anemia is a common complication in critically ill patients. Contributing factors include sepsis, frequent blood samples, surgical blood loss, immune mediated functional iron deficiency, decreased erythropoietin (EPO) production, reduced RBC life span, and active bleeding. Whether exogenous EPO improves clinical outcomes for critically ill patients is not clear.
8. Anemia is one of the most prevalent clinical problems in the elderly, although not an inevitable complication of aging. Anemia is associated with an increased risk of hospitalization and mortality, reduced quality of life, and decreased physical functioning in the elderly.
9. IDA is a leading cause of infant morbidity and mortality. Age- and sex-adjusted norms must be used in the interpretation of laboratory results for pediatric patients. Primary prevention of IDA is the goal. A therapeutic trial of oral iron is the standard of care.
10. Hemolytic anemia results in decreased survival of RBCs secondary to destruction in the spleen or circulation. Treatment is directed toward correcting or controlling the underlying pathology.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

Anemia affects a large part of the world's population. According to the World Health Organization, almost 1.6 billion people (25% of the world's population) are anemic. Anemia is defined by the World Health Organization as hemoglobin (Hb) <13 g/dL (<130 g/L; <8.07 mmol/L) in men or <12 g/dL (<120 g/L; <7.45 mmol/L) in

women. In the United States approximately 3.5 million Americans have anemia based on self-reported data from the National Center for Health Statistics. It is estimated that millions of people are unaware they have anemia, making it one of the most underdiagnosed conditions in the United States. Iron deficiency is considered to be the leading cause of anemia worldwide, accounting for as many as 50% of cases.[1] Recent data have shown that overall anemia has declined in the United States in preschool-aged children and women of childbearing age over the past 20 years. However, the prevalence of iron-deficiency anemia did not change significantly in these groups and the difference remains unclear.[2] Although nutritional deficiencies are less common in the United States, obesity surgery, which can cause deficiencies, is becoming increasingly common. Gastric bypass may result in folate, vitamin B_{12}, and iron deficiencies. Prevalence data are confounded by the lack of a standardized definition of anemia and lack of screening guidelines for several populations. The U.S. Preventive Services Task Force (USPSTF) guidelines for pregnant women recommend routine screening for iron-deficiency anemia (IDA).

Anemia is not an innocent bystander; it may affect both length and quality of life. Retrospective observational studies of hemodialysis patients and heart failure patients suggest that anemia is an independent risk factor for mortality.[3] In addition, anemia significantly influences morbidity, as shown for patients with end-stage renal disease, chronic kidney disease, and heart failure.[4] Anemia is associated with psychomotor and cognitive abnormalities in children. Similarly, among adults, anemia is associated with cognitive dysfunction in patients with renal failure, with those having cancer, and with community-dwelling elders.[5] Anemia during pregnancy is associated with increased risk for low birth weights, preterm delivery, and perinatal mortality.[6] Maternal IDA may be associated with postpartum depression and poor performance by offspring on mental and psychomotor tests. The effect of treatment on patient outcomes must be the focus of research on each specific type of anemia. Global goals of treatment in anemic patients are to alleviate signs and symptoms, correct the underlying etiology, and prevent recurrence of anemia.

1 Anemia is a group of diseases characterized by a decrease in either Hb or circulating red blood cells (RBCs), resulting in reduced oxygen-carrying capacity of the blood. Anemia can result from inadequate RBC production, increased RBC destruction, or blood loss. It can be a manifestation of a host of systemic disorders, such as infection, chronic renal disease, or malignancy. Because anemia is often a sign of underlying pathology, rapid diagnosis of the cause is essential.

Anemia can be classified on the basis of the morphology of the RBCs, etiology, or pathophysiology (see Table 109–1 for examples). This chapter focuses on IDA, anemia associated with vitamin B_{12} or folic acid deficiency, and anemia of chronic disease (ACD). Characteristic changes in the size of RBCs seen in erythrocyte indices can be the first step in the morphologic classification and understanding of the anemia.

TABLE 109-1 Classification Systems for Anemias

- I. Morphology
  - Macrocytic anemias
    - Megaloblastic anemias
      - Vitamin B_{12} deficiency
      - Folic acid deficiency anemia
  - Microcytic hypochromic anemias
    - Iron-deficiency anemia
    - Genetic anomaly
      - Sickle cell anemia
      - Thalassemia
      - Other hemoglobinopathies (abnormal hemoglobins)
  - Normocytic anemias
    - Recent blood loss
    - Hemolysis
    - Bone marrow failure
    - Anemia of chronic disease
  - Renal failure
  - Endocrine disorders
  - Myelodysplastic anemias
- II. Etiology
  - Deficiency
    - Iron
    - Vitamin B_{12}
    - Folic acid
    - Pyridoxine
  - Central, caused by impaired bone marrow function
    - Anemia of chronic disease
    - Anemia of the elderly
    - Malignant bone marrow disorders
  - Peripheral
    - Bleeding (hemorrhage)
    - Hemolysis (hemolytic anemias)
- III. Pathophysiology
  - Excessive blood loss
    - Recent hemorrhage
    - Trauma
    - Peptic ulcer
    - Gastritis
    - Hemorrhoids
  - Chronic hemorrhage
    - Vaginal bleeding
    - Peptic ulcer
    - Intestinal parasites
    - Aspirin and other nonsteroidal antiinflammatory agents
  - Excessive RBC destruction
    - Extracorpuscular (outside the cell) factors
      - RBC antibodies
      - Drugs
      - Physical trauma to RBC (artificial valves)
      - Excessive sequestration in the spleen
  - Intracorpuscular factors
    - Heredity
    - Disorders of hemoglobin synthesis
  - Inadequate production of mature RBCs
    - Deficiency of nutrients (B_{12}, folic acid, iron, protein)
    - Deficiency of erythroblasts
      - Aplastic anemia
      - Isolated (often transient) erythroblastopenia
      - Folic acid antagonists
      - Antibodies
  - Conditions with infiltration of bone marrow
    - Lymphoma
    - Leukemia
    - Myelofibrosis
    - Carcinoma
  - Endocrine abnormalities
    - Hypothyroidism
    - Adrenal insufficiency
    - Pituitary insufficiency
  - Chronic renal disease
  - Chronic inflammatory disease
    - Granulomatous diseases
    - Collagen vascular diseases
  - Hepatic disease

RBC, red blood cell.

Anemia is classified by RBC size as macrocytic, normocytic, or microcytic. Vitamin B_{12} deficiency and folic acid deficiency both are macrocytic anemias. An example of a microcytic anemia is iron deficiency, whereas a normocytic anemia may be associated with recent blood loss or chronic disease. More than one anemia and etiology can occur concurrently. Inclusion of the underlying cause of the anemia makes diagnostic terminology easier to understand (e.g., microcytic anemia secondary to iron deficiency).

Microcytic anemias are pathogenically a result of a quantitative deficiency in Hb synthesis, usually due to iron deficiency or impaired iron utilization. As a result, erythrocytes containing insufficient Hb are formed. Microcytosis and hypochromia are the morphologic abnormalities that provide evidence of impaired Hb synthesis.

Macrocytic anemias can be divided into megaloblastic and nonmegaloblastic anemias. The type of macrocytic anemia can be distinguished microscopically by peripheral blood smear examination. Megaloblasts are distinctive cells that express a biochemical abnormality of retarded DNA synthesis, resulting in unbalanced cell growth. Megaloblastic anemias may affect all hematopoietic cell lines. The most common cause of megaloblastic anemia is vitamin B_{12} and/or folate deficiency. Nonmegaloblastic macrocytic anemias may arise from liver disease, hypothyroidism, hemolytic processes, and alcoholism. Hemolytic anemias often are macrocytic, reflecting the increased numbers of circulating reticulocytes, which are larger on average than mature red cells.

MATURATION AND DEVELOPMENT OF RED BLOOD CELLS

In adults, RBCs are formed in the marrow of the vertebrae, ribs, sternum, clavicle, pelvic (iliac) crest, and proximal epiphyses of the long bones. In children, most bone marrow space is hematopoietically active to meet increased RBC requirements.

In normal RBC formation, a pluripotent stem cell yields an erythroid burst-forming unit. Erythropoietin (EPO) and cytokines such as interleukin-3 and granulocyte–macrophage colony-stimulating factor stimulate this cell to form an erythroid colony-forming unit in the marrow. The erythroid colony-forming unit is sensitive to EPO and produces proerythroblasts. Subsequent divisions yield basophilic erythroblasts, polychromatic erythroblasts, pyknotic erythroblasts, reticulocytes, and finally erythrocytes. During this process, the nucleus becomes smaller with each division, finally disappearing in the normal erythrocyte (Fig. 109–1). Hb and iron are incorporated into the gradually maturing RBC, which eventually is released from the marrow into the circulating blood as a reticulocyte. The maturation process usually takes approximately 1 week. The reticulocyte loses its nucleus and becomes an erythrocyte within several days. The circulating erythrocyte is a nonnucleated, nondividing cell. More than 90% of the protein content of the erythrocyte consists of the oxygen-carrying molecule Hb. Erythrocytes have a normal survival time of 120 days.[7]

STIMULATION OF ERYTHROPOIESIS

The hormone EPO, 90% of which is produced by the kidneys, initiates and stimulates the production of RBCs. Erythropoiesis is regulated by a feedback loop. The main mechanism of action of EPO is preventing apoptosis, or programmed cell death, of erythroid precursor cells and allowing their proliferation and subsequent maturation. A decrease in tissue oxygen concentration signals the kidneys to increase the production and release of EPO into the plasma, which increases production and maturation of RBCs.

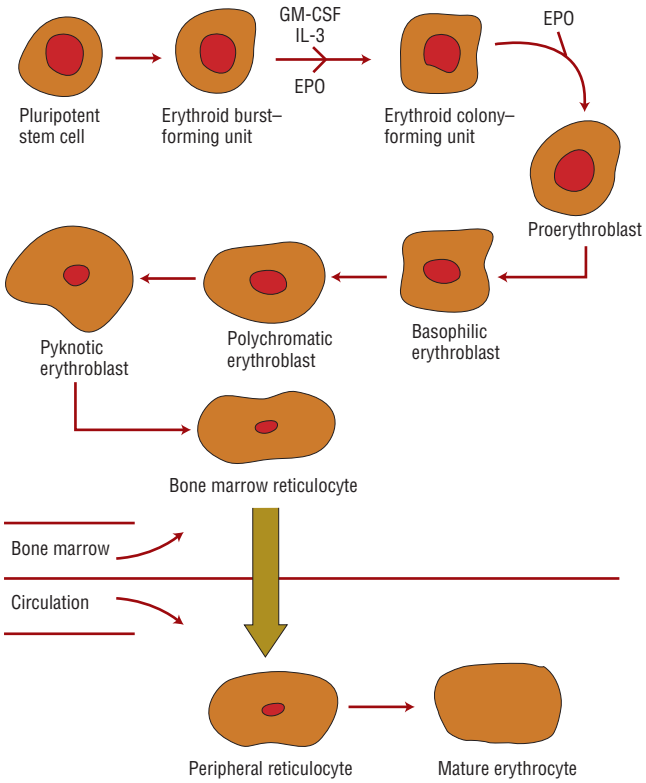

FIGURE 109-1. Erythrocyte maturation sequence (EPO, erythropoietin; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-3, interleukin-3).

Under normal circumstances, the RBC mass is kept at an almost constant level by EPO matching new erythrocyte production to the natural rate of loss of RBCs. A feedback mechanism stops further RBC nucleic acid synthesis, causing an earlier release of reticulocytes. This feedback loop and summary of erythropoiesis are shown in Figure 109–2. Early appearance of large quantities of reticulocytes in the peripheral circulation (reticulocytosis) is an indication of increased RBC production.[7]

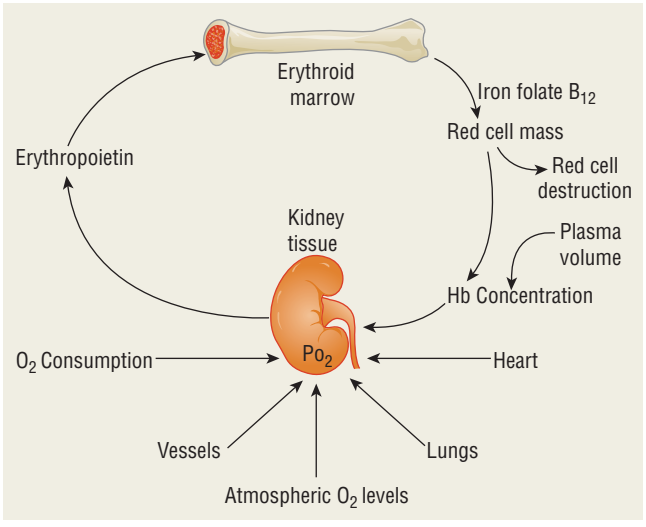

FIGURE 109-2. Physiologic regulation of red cell production by tissue oxygen tension. *(Reproduced with permission from Adamson JW., Longo DL. Anemia and polycythemia. SYNTHESIS OF HEMOGLOBIN

Hb consists of a protein component with two α-chains and two β-chains. Each chain is linked to a heme group consisting of a porphyrin ring structure with an iron atom chelated at its center, which is capable of binding oxygen. The initial step in the synthesis of heme from the substrate succinyl CoA and glycine requires the presence of pyridoxine phosphate (vitamin B_6) as a catalyst. Following its synthesis in the cytoplasmic mitochondria of the RBC, heme diffuses into the extramitochondrial space, combines with the completed α- and β-chains, and forms Hb. When hemolytic destruction of RBCs exceeds marrow production capacity and anemia develops, the Hb value decreases to a steady-state level at which production is equal to destruction. Hb values in these hemolytic anemias, such as sickle cell anemia (see Chap. 111), will remain stable unless other factors further shorten the RBC life span.

The affinity of Hb for oxygen is influenced by three intracellular components and by temperature. Increasing concentrations of hydrogen ion (decreasing pH), carbon dioxide, and 2,3-bisphosphoglycerate, together with increased temperature, all enhance the ability of Hb to release oxygen into tissue by decreasing oxygen affinity. This physiologic compensation also increases plasma volume, which can increase tissue perfusion.[8]

INCORPORATION OF IRON INTO HEME

Iron is an essential part of hemoglobin. The specific plasma transport protein transferrin delivers iron to the bone marrow for incorporation into the Hb molecule. Transferrin enters cells by binding to transferrin receptors, which circulate and then attach to cells needing iron. Conversely, there are fewer transferrin receptors on the surface of cells that do not need iron, thus preventing iron-replete cells from receiving excess iron.[9]

Circulating transferrin normally is approximately 30% saturated with iron. Transferrin delivers extra iron to other body storage sites, such as the liver, marrow, and spleen, for later use. This iron is stored within macrophages as ferritin or hemosiderin. Ferritin consists of a Fe^{3+} hydroxyphosphate core surrounded by a protein shell called *apoferritin*. Hemosiderin can be described as compacted ferritin molecules with an even greater iron-to-protein shell ratio. Physiologically it is a more stable, but less available, form of storage iron. Total body iron storage is generally reflected by ferritin levels.[10]

NORMAL DESTRUCTION OF RED BLOOD CELLS

Phagocytic breakdown destroys older blood cells, primarily in the spleen but also in the marrow (Fig. 109–3). Amino acids from the globin chains return to an amino acid pool; heme oxygenase acts on the porphyrin heme structure to form biliverdin and to release its iron. Iron returns to the iron pool to be reused, although biliverdin is further catabolized to bilirubin. The bilirubin is released into the plasma, where it binds to albumin and is transported to the liver for glucuronide conjugation and excretion via bile. If the liver is unable to perform the conjugation, as occurs with intrinsic liver disease or oversaturation of conjugation enzymes by excessive cell hemolysis, the result is an elevated *indirect* (unconjugated) bilirubin. If the biliary excretion pathway for conjugated bilirubin is obstructed, an elevated *direct* bilirubin results. Comparison of direct and indirect bilirubin values helps to determine if the defect in bilirubin clearance occurs before or after bilirubin enters the liver. The Hb in RBCs, which is destroyed by intravascular hemolysis, becomes attached to haptoglobin and is carried back to the marrow for processing in the normal manner.[11]

DIAGNOSIS OF ANEMIA

GENERAL PRESENTATION

History, physical examination, and laboratory testing are used in the evaluation of the patient with anemia. The workup determines if the patient is bleeding and investigates potential causes of the anemia, such as increased RBC destruction, bone marrow suppression, or iron deficiency. Diet can also be important in identifying causes of anemia. Additionally, information about concurrent nonhematologic disease states and a drug ingestion history are essential when evaluating the cause of the anemia (see Chap. 112). History of blood transfusions and exposure to toxic chemicals also should be obtained.

Presenting signs and symptoms of anemia depend on the rate of development and the age of the patient, as well as the cardiovascular status of the patient. Severity of symptoms does not always correlate with the degree of anemia. Healthy patients may acclimate to very low Hb concentrations if the anemia develops slowly. Mild anemia often is associated with no clinical symptoms and may be found incidentally upon obtaining a complete blood count (CBC) for other reasons. The signs and symptoms in elderly patients with anemia may be attributed to their age or concomitant disease states. The elderly may not tolerate levels of Hb tolerated by younger persons. Patients with cardiac or pulmonary disease may be less tolerant of mild anemia. Premature infants with anemia

may be asymptomatic or have tachycardia, poor weight gain, increased supplemental oxygen needs, or increased episodes of apnea or bradycardia.

CLINICAL PRESENTATION OF ANEMIA

General

- Patients may be asymptomatic or have vague complaints
- Patients with vitamin B_{12} deficiency may develop neurologic consequences
- In ACD, signs and symptoms of the underlying disorder often overshadow those of the anemia

Symptoms

- Decreased exercise tolerance
- Fatigue
- Dizziness
- Irritability
- Weakness
- Palpitations
- Vertigo
- Shortness of breath
- Chest pain
- Neurologic symptoms in vitamin B_{12} deficiency

Signs

- Tachycardia
- Pale appearance (most prominent in conjunctivae)
- Decreased mental acuity
- Increased intensity of some cardiac valvular murmurs
- Diminished vibratory sense or gait abnormality in vitamin B_{12} deficiency

Laboratory Tests

- Hb, hematocrit (Hct), and RBC indices may remain normal early in the disease and then decrease as the anemia progresses
- Serum iron is low in IDA and ACD
- Ferritin levels are low in IDA and normal to increased in ACD
- TIBC is high in IDA and is low or normal in ACD
- Mean cell volume is elevated in vitamin B_{12} deficiency and folate deficiency
- Vitamin B_{12} and folate levels are low in their respective types of anemia
- Homocysteine is elevated in vitamin B_{12} deficiency and folate deficiency
- Methylmalonic acid is elevated in vitamin B_{12} deficiency

Other Diagnostic Tests

- Schilling test may help uncover intrinsic factor deficiency
- Bone marrow testing with iron staining can indicate low iron levels in IDA and adequate stores in ACD

2 Anemia of rapid onset is most likely to present with cardiorespiratory symptoms such as tachycardia, palpitations, angina, hypotension, lightheadedness, and breathlessness due to decreased oxygen delivery to tissues or hypovolemia in those with acute bleeding.

If onset is more chronic, presenting symptoms may include fatigue, weakness, headache, symptoms of heart failure, vertigo, faintness, sensitivity to cold, pallor, and loss of skin tone. Traditional signs of anemia, such as pallor, have limited sensitivity, and specificity and may be misinterpreted. With chronic bleeding, there is time for equilibration within the extravascular space.

Possible manifestations of IDA include glossal pain, smooth tongue, reduced salivary flow, pica (compulsive eating of nonfood items), and pagophagia (compulsive eating of ice). These symptoms are not likely to appear until the Hb concentration falls to a level of 9 g/dL (90 g/L; 5.59 mmol/L) or below.

Neurologic findings in vitamin B_{12} deficiency, which often precede hematologic findings, may be partly due to impairment of conversion of homocysteine to methionine, as methionine is necessary for production of choline and choline-containing phospholipids. Neurologic effects of vitamin B_{12} deficiency may occur even in the absence of anemia. Early neurologic findings include numbness and paraesthesias, then peripheral neuropathy, ataxia, diminished vibratory sense, decreased proprioception, and imbalance, as demyelination of the dorsal columns and corticospinal tract develop. Vision changes may result from optic nerve involvement. Psychiatric findings include irritability, personality changes, memory impairment, depression, and, infrequently, psychosis. Pernicious anemia is associated with increased risk of gastric cancer.

Anemia associated with folate deficiency is typically macrocytic but, unlike B_{12} deficiency, occurs without neurological symptoms. Although the symptoms of anemia will improve with folate replacement and a partial hematologic response will occur, the neurologic manifestations of vitamin B_{12} deficiency will not be reversed with folic acid replacement therapy and consequently may progress or become irreversible if not treated.

LABORATORY EVALUATION

The initial evaluation of anemia involves a CBC (including RBC indices), reticulocyte index, and examination of a stool sample for occult blood. The results of the preliminary evaluation determine the need for other studies, such as examination of a peripheral blood smear. Based on laboratory test results, anemia can be categorized into three functional defects: RBC production failure (hypoproliferative), cell maturation ineffectiveness, or increased RBC destruction or loss.

Table 109–2 lists normal hematologic values, although these values may differ in certain populations such as individuals living at high altitudes and endurance athletes.

Figure 109–4 shows a broad, general algorithm for the diagnosis of anemia based on laboratory data. There are many exceptions and additions to this algorithm, but it can serve as a guide to the typical presentation of common types and causes of anemia. The algorithm is less useful in the presence of more than one cause of anemia.

Hemoglobin

Values given for Hb represent the amount of Hb per volume of whole blood. The higher values seen in males are due to stimulation of RBC production by androgenic steroids, whereas the lower values in females are due to decrease in Hb as a result of blood loss during menstruation. The Hb level can be used as a very rough estimate of the oxygen-carrying capacity of blood. Hb levels may be diminished because of a decreased quantity of Hb per RBC or because of a decrease in the actual number of RBCs. In pregnancy, Hb may not reflect red cell mass changes.

Hematocrit

Expressed as a percentage, hematocrit (Hct) is the actual volume of RBCs in a unit volume of whole blood. In general, it is

TABLE 109-2 Normal Hematologic Values

Test	Reference Range 2–6	6–12	12–18	18–49
Hemoglobin (g/dL)	11.5–15.5	11.5–15.5	M 13.0–16.0 F 12.0–16.0	M 13.5–17.5 F 12.0–16.0
Hematocrit (%)	34–40	35–45	M 37–49 F 36–46	M 41–53 F 36–46
MCV (fL)	75–87	77–95	M 78–98 F 78–102	80–100
MCHC (%)	–	31–37	31–37	31–37

[a]Varies by assay method.

approximately three times the Hb value. An alteration in this ratio may occur with abnormal cell size or shape and often indicates the pathology. A low Hct indicates a reduction in either the number or the size of RBCs or an increase in plasma volume.

Red Blood Cell Count

The RBC count is an indirect estimate of the Hb content of the blood; it is an actual count of RBCs per unit of blood.

Red Blood Cell Indices

Wintrobe indices describe the size and Hb content of the RBCs and are calculated from the Hb, Hct, and RBC count. RBC indices, such as mean corpuscular volume (MCV) and mean corpuscular Hb (MCH), are single mean values that do not express the variation that can occur in cells.

Mean Cell Volume (Hct/RBC Count) MCV represents the average volume of RBCs. It may reflect changes in MCH. Cells are considered macrocytic if they are larger than normal, microcytic if they are smaller than normal, and normocytic if their size falls within normal limits. Folic acid and vitamin B_{12} deficiency anemias yield macrocytic cells, whereas iron deficiency and thalassemia are examples of microcytic anemias. MCV is falsely elevated in the presence of cold agglutinins and hyperglycemia. When IDA (decreased MCV) is accompanied by folate deficiency (increased MCV), the overall MCV may be normal. Failure to understand that the MCV represents an average RBC size creates the potential for overlooking some causes of the anemia.

Mean Cell Hemoglobin (Hb/RBC Count) MCH is the amount of Hb in a RBC. It reflects the adequacy of iron supply. Two morphologic changes, microcytosis and hypochromia, can reduce MCH. A microcytic cell contains less Hb because it is a smaller cell, while a hypochromic cell has a low MCH because of the decreased amount of Hb present in the cell. Cells can be both microcytic and hypochromic, as seen with IDA. The MCH alone can not distinguish between microcytosis and hypochromia. The most common cause of an elevated MCH is macrocytosis (e.g., vitamin B_{12} or folate deficiency).

Mean Cell Hemoglobin Concentration (Hb/Hct) The concentration of Hb per volume of cells is the mean corpuscular Hb concentration (MCHC). Because MCHC is independent of cell size, it is more useful than MCH in distinguishing between microcytosis and hypochromia. A low MCHC indicates hypochromia; a microcyte with a normal Hb concentration will have a low MCH but a normal MCHC. A decreased MCHC is seen most often in IDA.

Total Reticulocyte Count

The total reticulocyte count is an indirect assessment of new RBC production. It reflects how quickly immature RBCs (reticulocytes) are produced by bone marrow and released into the blood. Reticulocytes circulate in the blood approximately 2 days before maturing into RBCs. About 1% of RBCs are normally replaced daily, representing a reticulocyte count of 1%. The reticulocyte count in normocytic anemia can differentiate hypoproliferative marrow from a compensatory marrow response to an anemia. A lack of reticulocytosis in anemia indicates impaired RBC production. Examples include iron deficiency, B_{12} deficiency, ACD, malnutrition, renal insufficiency, and malignancy. A high reticulocyte count may be seen in acute blood loss or hemolysis. A patient's Hct occasionally decreases while the absolute number of reticulocytes remains the same, resulting in a falsely elevated reticulocyte percentage. Multiplying the reticulocyte percentage by the patient's Hct and then dividing the product by an average normal Hct (for men or women) produces a corrected percentage of reticulocytes. When the reticulocyte count is >2.5%, hemolysis may be present.

Red Blood Cell Distribution Width

The higher the RBC distribution width (RDW) is, the more variable is the size of the RBCs. The RDW increases in early IDA because of the release of large, immature, nucleated RBCs to compensate for the anemia, but this change is not specific for IDA. The RDW also can be helpful in the diagnosis of a mixed anemia. A patient can have a normal MCV yet have a wide RDW. This finding indicates the presence of microcytes and macrocytes, which would yield a "normal" average RBC size. Use of RDW to distinguish IDA from ACD is not recommended.

Peripheral Blood Smear

The peripheral blood smear can supplement other clinical data and help establish a diagnosis. Peripheral blood smears provide information on the functional status of the bone marrow and defects in RBC production. Additionally, it provides information on variations in cell size (anisocytosis) and shape (poikilocytosis). Automated blood counters, used for the CBC, can flag specific RBC changes that can be confirmed by a peripheral blood smear. Blood smears are placed on a microscope slide and stained as appropriate. Morphologic examination includes assessment of size, shape, and color. The extent of anisocytosis correlates with increased range of cell sizes. Poikilocytosis suggests a defect in the maturation of RBC precursors in the bone marrow.

Serum Iron

The level of serum iron is the concentration of iron bound to transferrin. Transferrin is normally approximately one-third bound (saturated) to iron. The serum iron level of many patients with IDA may remain within the lower limits of normal because a considerable amount of time is required to deplete iron stores. Serum iron levels show diurnal variation (higher in the morning, lower in the afternoon), but this variation is probably not clinically significant in

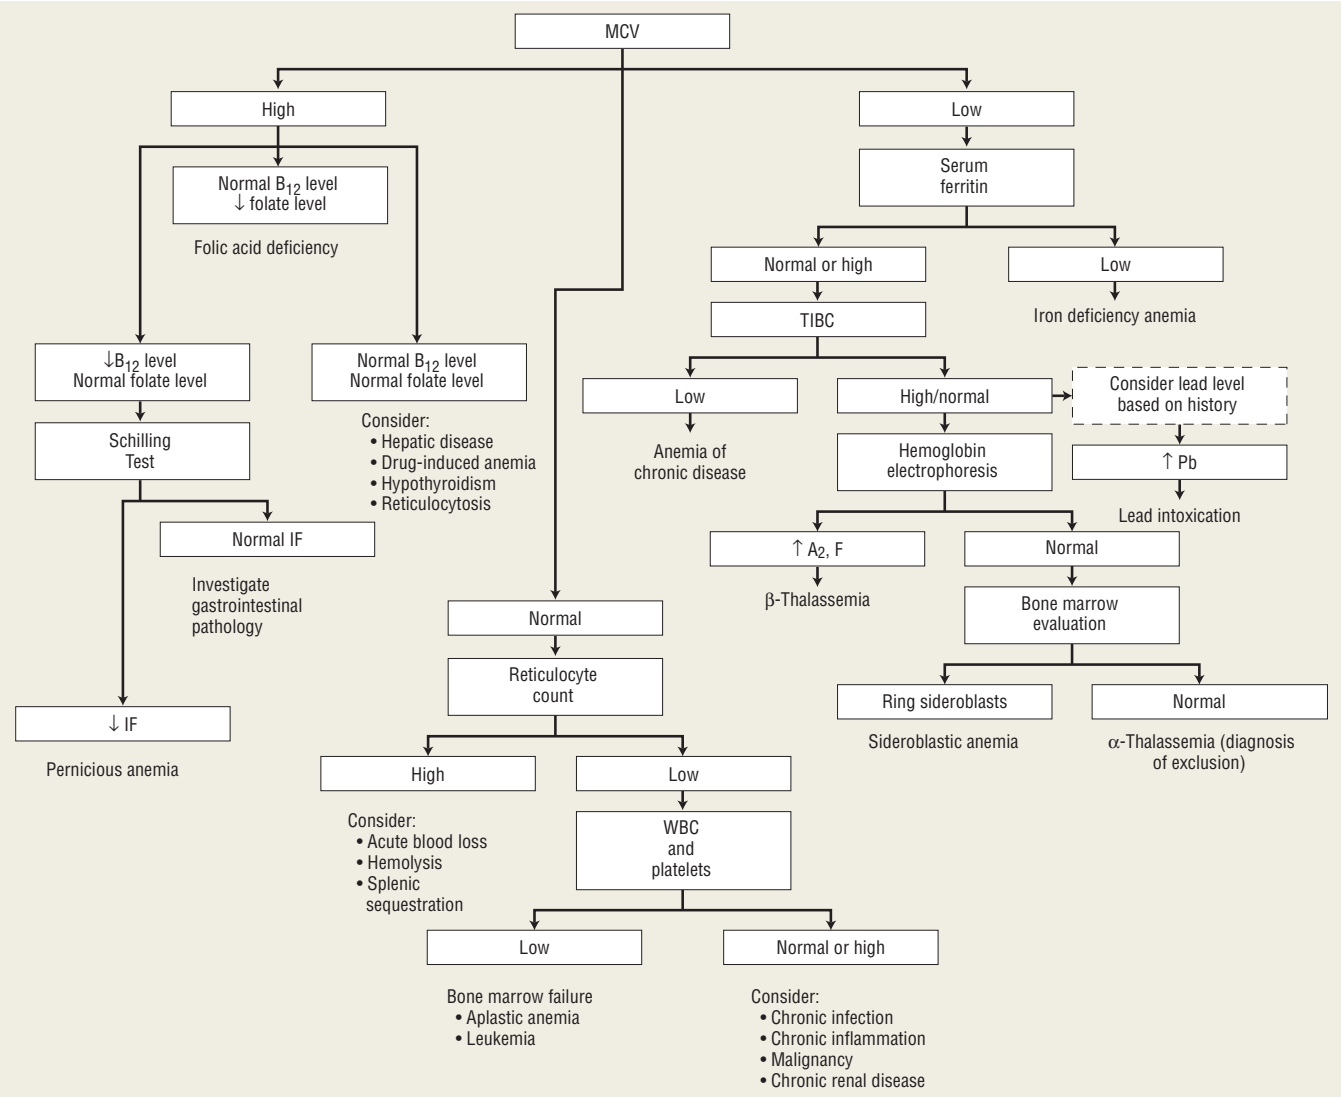

FIGURE 109-4. General algorithm for diagnosis of anemias (↑, increased; ↓, decreased; A_2, hemoglobin A_2; F, hemoglobin F; IF, intrinsic factor; MCV, mean corpuscular volume; Pb, lead; TIBC, total iron-binding capacity; WBC, white blood cells).

timing of levels.[10] Since serum iron levels are decreased by infection and inflammation, serum iron levels are best interpreted in conjunction with the TIBC. The serum iron level decreases with IDA and ACD and increases with hemolytic anemias and iron overload.

Total Iron-Binding Capacity

An indirect measurement of the iron-binding capacity of serum transferrin, total iron-binding capacity (TIBC) evaluation is performed by adding an excess of iron to plasma to saturate all transferrin with iron. Each transferrin molecule can carry two iron atoms. Normally, approximately 30% of available iron-binding sites are filled. With this laboratory test, all binding sites are filled to measure TIBC. The excess (unbound) iron is then removed and the serum iron concentration determined. Unlike the serum iron level, the TIBC does not fluctuate over hours or days. TIBC usually is higher than normal when body iron stores are low. The finding of a low serum iron level and a high TIBC suggests IDA. The TIBC is actually a measurement of protein serum transferrin, which can be affected by a variety of factors. Patients with infection, malignancy, inflammation, liver disease, and uremia may have a decreased TIBC and a decreased serum iron level, which are consistent with the diagnosis of ACD. Oral contraceptive use and pregnancy can increase TIBC because serum transferrin production is increased with a variety of other proteins.

Percentage Transferrin Saturation

The ratio of serum iron level to TIBC indicates transferrin saturation. It reflects the extent to which iron-binding sites are occupied on transferrin and indicates the amount of iron readily available for erythropoiesis. It is expressed as a percentage, as described in the following formula:

$$\text{Transferrin saturation} = \frac{\text{serum iron}}{\text{TIBC}} \times 100$$

Transferrin normally is 20% to 50% saturated with iron. In IDA, transferrin saturation of 15% or lower is commonly seen.[10] Transferrin saturation is a less sensitive and specific marker of iron deficiency than are ferritin levels.

Serum Ferritin

The concentration of ferritin (storage iron) is proportional to total iron stores and therefore is the best indicator of iron deficiency or iron overload. Ferritin levels indicate the amount of iron stored in

the liver, spleen, and bone marrow cells. Low serum ferritin levels are virtually diagnostic of IDA because they decrease only in association with IDA. In contrast, serum iron levels may decrease in both IDA and ACD. Serum ferritin is an acute phase reactant; so chronic infection or inflammation can increase its concentration independent of iron status, masking depleted tissue stores. This limits the utility of the serum ferritin if the level is normal or high for a chronically ill patient. For these patients, iron, even if present in these tissue stores, may not be available for erythropoiesis.

Soluble Transferrin Receptor

The soluble transferrin receptor (sTfR) assay is a laboratory test considered a sensitive, early, highly quantitative marker of iron depletion. The sTfR concentration is inversely correlated with tissue iron stores, and elevated levels are predictive of iron deficiency. Unlike ferritin, the sTfR is not an acute phase reactant; so its level remains normal for patients with chronic disease. It may be a useful test for distinguishing ACD from IDA.[10] The major limitation of this test is that it is not widely available in many laboratories.

Folic Acid

The results of folic acid measurements vary depending on the assay method used. Decreased serum folic acid levels indicate a folate deficiency megaloblastic anemia that may coexist with a vitamin B_{12} deficiency anemia. Erythrocyte folic acid levels are less volatile than serum levels because they are slow to decrease in an acute process such as drug-induced folic acid deficiency and slow to increase with oral folic acid replacement. In addition, erythrocyte folic acid levels have the theoretical advantage of less susceptibility to rapid changes in diet and alcohol intake. Limitations with sensitivity and specificity do exist with measurements of erythrocyte folate. It has been proposed that serum folate assay levels be drawn for patients with MCV >110 fL or for patients with a lower MCV and clinical features suggesting a macrocytic anemia. If the serum folate concentration is normal for a patient with suspected folate deficiency, then the red cell folate level should be measured.[12]

Vitamin B_{12}

Low levels of vitamin B_{12} (cyanocobalamin) indicate deficiency. However, a deficiency may exist prior to the recognition of low serum levels. Serum values are maintained at the expense of vitamin B_{12} tissue stores. Vitamin B_{12} and folate deficiency may overlap, thus serum levels of both vitamins should be determined. Vitamin B_{12} levels may be falsely low with folate deficiency, pregnancy, and use of oral contraceptives.[13]

Schilling Test

The purpose of the rarely used Schilling urinary excretion test is to diagnose vitamin B_{12} deficiency anemia caused by a B_{12} absorption defect resulting from a lack of intrinsic factor (pernicious anemia). The patient initially receives an oral dose of radiolabeled vitamin B_{12}. Two hours later, the patient receives a large intramuscular dose of nonlabeled vitamin B_{12} to saturate plasma transport proteins. Any excess vitamin B_{12} that is not taken up by the transport proteins or stored in the liver is excreted in the urine. A 24-hour urine collection then is measured for radioactivity. If production of gastrointestinal intrinsic factor is sufficient, the radiolabeled B_{12} will be absorbed initially, displaced by the injected B_{12}, and excreted in the urine.

If oral absorption is impaired, stage 2 of the test is conducted 5 to 7 days later. The second stage of the Schilling test differentiates inadequate secretion of intrinsic factor by the stomach from an abnormality in absorption by the ileum. Generally, the finding of abnormal results for stage 1 followed by a normal result in stage 2 is consistent with pernicious anemia. If the results in part 2 still are low, then the third stage of the test is conducted to determine whether the cause of the deficiency is bacterial overgrowth or ileal disease.[14]

Homocysteine

Vitamin B_{12} and folate both are required for conversion of homocysteine to methionine. Increased serum homocysteine may suggest vitamin B_{12} or folate deficiency. Homocysteine levels also can be elevated in patients with vitamin B_6 deficiency, renal failure, hypothyroidism, or a genetic defect in cystathionine β-synthase.[15] Additionally, elevated levels have been caused by medications, including nicotinic acid, theophylline, methotrexate, and L-dopa.

Methylmalonic Acid

A vitamin B_{12} coenzyme is needed to convert methylmalonyl coenzyme A to succinyl coenzyme A. Patients with vitamin B_{12} deficiency may have increased concentrations of serum methylmalonic acid (MMA), which is a more specific marker for vitamin B_{12} deficiency than homocysteine. MMA levels are not elevated in folate deficiency because folate does not participate in MMA metabolism. Levels of both MMA and homocysteine usually are elevated prior to the development of hematologic abnormalities and reductions in serum vitamin B_{12} levels.[13] MMA levels must be interpreted cautiously for patients with renal disease and hypovolemia because the levels may be elevated due to decreased urinary excretion.

Coombs Test

Antiglobulin tests, also called *Coombs tests*, indicate hemolytic anemia caused by an immune response. A direct Coombs test detects antibodies bound to erythrocytes, whereas an indirect Coombs test measures antibodies present in the serum. A positive finding on a direct Coombs test usually is indicative of antibody-mediated hemolysis.

Erythropoietin Levels

Healthy individuals require 5 to 30 milliunits/mL of EPO to maintain normal Hb and Hct concentrations. Endogenous EPO levels can increase during hypoxia or anemia, but this marked increase does not occur for patients with significant renal disease, for patients receiving chemotherapy, and for patients with acquired immunodeficiency syndrome (AIDS), especially those taking zidovudine. These patients will have an EPO response that is insufficient to correct their anemia.

SPECIFIC ANEMIAS

IRON-DEFICIENCY ANEMIA

Epidemiology

Iron deficiency is the most common nutritional deficiency in developing and developed countries. Data from the National Health and Nutrition Examination Survey (NHANES) indicates the prevalence of IDA in young children and women of childbearing age is 1.2% and 4.5%, respectively.[2] The normal ranges for Hb and Hct are so wide that a patient may lose up to 15% of RBC mass and still have a Hct within the normal range. Therefore, iron deficiency may precede the appearance of anemia.

Iron Balance

The normal iron content of the body is approximately 3 to 4 g. Iron is a component of Hb, myoglobin, and cytochromes. Approximately

2 g of the iron exists in the form of Hb, and approximately 140 mg exists as iron-containing proteins such as myoglobin. Approximately 3 mg of iron is bound to transferrin in plasma, and 1,000 mg of iron exists as storage iron in the form of ferritin or hemosiderin. The rest of the iron is stored in other tissues such as cytochromes.[10] Due to the toxicity of inorganic iron, the body has an intricate system for iron absorption, transport, storage, assimilation, and elimination. Hepcidin is a regulator of intestinal iron absorption, iron recycling, and iron mobilization from hepatic stores. It is a peptide made in the liver, distributed in plasma, and excreted in urine. Hepcidin inhibits efflux of iron through ferroportin. Hepcidin synthesis is increased by iron loading and decreased by anemia and hypoxia. Hepcidin is induced during infections and inflammation, which allows iron to sequester in macrophages, hepatocytes, and enterocytes.[16] As a result, hepcidin is likely an important mediator of ACD.

Most people lose approximately 1 mg of iron daily. Menstruating women can lose up to 0.6% to 2.5% more per day. Pregnancy requires an additional 700 mg of iron and a blood donation can result in as much as 250 mg of iron loss;[17] these populations are at higher risk for deficiency.

Iron is best absorbed in its ferrous (Fe^{2+}) form. The normal daily Western diet contains approximately 12 to 15 mg of iron, mainly in the ferric (Fe^{3+}) nonabsorbed form. After iron is ionized by stomach acid and then reduced to the Fe^{2+} state, it is absorbed primarily in the duodenum, and to a smaller extent in the jejunum, via intestinal mucosal cell uptake. Subsequently, it is transferred across the cell into the plasma. Iron absorption is not directly correlated to iron intake. As physiologic iron levels decrease, gastrointestinal absorption of iron increases.

The daily recommended dietary allowance for iron is 8 mg in adult males and postmenopausal females and 18 mg in menstruating females. Children require more iron because of growth-related increases in blood volume, and pregnant women have an increased iron demand brought about by fetal development. In the absence of hemachromatosis, iron overload does not occur, because only the amount of iron lost per day is absorbed. The amount of iron absorbed from food depends on the body stores, the rate of RBC production, the type of iron provided in the diet, and the presence of any substances that may enhance or inhibit iron absorption.

Heme iron, which is found in meat, fish, and poultry, is approximately three times more absorbable than the nonheme iron found in vegetables, fruits, dried beans, nuts, grain products, and dietary supplements. Gastric acid and other dietary components such as ascorbic acid increase the absorption of nonheme iron. Dietary components that form insoluble complexes with iron (phytates, tannates, and phosphates) decrease absorption. Phytates, a natural component of grains, brans, and some vegetables, can form poorly absorbed complexes and partially explain the increased prevalence of IDA in poorer countries, where grains and vegetables compose a disproportionate amount of the normal diet. Polyphenols bind the iron and decrease nonheme iron absorption when large amounts of tea or coffee are consumed with a meal. Although the mechanism is unknown, calcium inhibits absorption of both heme and nonheme iron. Finally, because gastric acid improves iron absorption, patients who have undergone a gastrectomy or have achlorhydria have decreased iron absorption.[18]

Etiology

Iron deficiency results from prolonged negative iron balance. This can occur due to increased iron demand or hematopoiesis, increased loss, or decreased intake/absorption. The onset of iron deficiency depends on an individual's initial iron stores and balance between iron absorption and loss. Multiple etiologic factors usually are involved. Certain groups at higher risk for iron deficiency include children younger than 2 years, adolescent girls, pregnant/lactating females, and those older than 65 years. Patients older than 65 years of age with IDA should be considered for screening for occult gastrointestinal cancer.[17] Blood loss must initially be considered a cause of IDA in adults. Blood loss may occur as a result of many disorders, including trauma, hemorrhoids, peptic ulcers, gastritis, gastrointestinal malignancies, arteriovenous malformations, diverticular disease, copious menstrual flow, nosebleeds, and postpartum bleeding. In less industrialized nations, the risks for developing IDA are largely related to dietary factors.

The USPSTF recommends routine screening for IDA in all pregnant women.[19] The USPSTF has concluded that evidence is insufficient to recommend for or against routine iron supplementation for nonanemic pregnant women.[19] However, iron deficiency in pregnant women is so common that the Centers for Disease Control and Prevention (CDC) guidelines recommend initiation of low-dose iron supplements or prenatal vitamins with 30 mg/day of iron at the woman's first prenatal visit.

Medication history, specifically regarding recent or past use of iron or hematinics, alcohol, corticosteroids, aspirin, and nonsteroidal antiinflammatory drugs, is a vital part of the history. Other possible causes of hypochromic microcytic anemia include ACD, thalassemia, sideroblastic anemia, and heavy metal (mostly lead) poisoning (Fig. 109–4).

Pathophysiology

Iron is vital to the function of all cells. It is a critical element in iron-containing enzymes such as the mitochondrial cytochrome system. Without iron, cells lose their capacity for electron transport and energy metabolism. Because iron is a cofactor for oxidative metabolism, dopamine and DNA synthesis, and free radical function in neutrophils, IDA can be associated with abnormal neurotransmitter function and altered immunologic and inflammatory defenses. Iron deficiency usually is the result of a long period of negative iron balance. Manifestations of iron deficiency occur in three stages. In the initial stage, iron stores are reduced without reduced serum iron levels and can be assessed with serum ferritin measurement. In this first stage, iron stores can be depleted without causing anemia. The stores allow iron to be utilized when there is an increased need for Hb synthesis. Once stores are depleted, there still is adequate iron from daily RBC turnover for Hb synthesis. Further iron losses would make the patient vulnerable to anemia development. In the second stage, iron deficiency occurs when iron stores are depleted, and Hb is above the lower limit of normal for the population but may be reduced for a given patient. This can be determined by serial CBC measurements. Findings include reduced transferrin saturation and increased TIBC. The third stage is IDA and occurs when the Hb falls to less than normal values.

Laboratory Findings

❸ Abnormal laboratory findings for patients with IDA generally include low serum iron and ferritin levels and high TIBC. The first apparent sign of iron deficiency is the increased RDW, although the finding is not specific to IDA. In the early stages of IDA, RBC size is not changed. Low ferritin concentration is the earliest and most sensitive indicator of iron deficiency. However, ferritin may not correlate with iron stores in the bone marrow because renal or hepatic disease, malignancies, infection, or inflammatory processes may increase ferritin values.[10] Hb, Hct, and RBC indices usually remain normal.

In the later stages of IDA, Hb and Hct fall below normal values, and a microcytic hypochromic anemia develops. Microcytosis may precede hypochromia, as erythropoiesis is programmed to maintain

normal Hb concentration in preference to cell size. As a result, even slightly abnormal Hb and Hct levels may indicate significant depletion of iron stores and should not be ignored. In terms of RBC indices, MCV is reduced earlier in IDA than Hb concentration.

Transferrin saturation (i.e., serum iron level divided by the TIBC) is useful for assessing IDA. Low values may indicate IDA, although low serum transferrin saturation values also may be present in inflammatory disorders. The TIBC may help to differentiate the diagnosis in these patients: TIBC >400 mcg/dL (71.6 mol/L) suggests IDA, whereas values <200 mcg/dL (35.8 mol/L) usually represent inflammatory disease. With continued progression of IDA, anisocytosis occurs and poikilocytosis develops, as seen on peripheral blood smear and indicated by increased RDW. In microcytic anemias due to all other causes, iron stores are detectable. Serum transferrin receptor can be used to diagnose iron-store depletion and defects in iron delivery to the marrow. An elevated serum transferrin receptor level would be expected in IDA and a normal level in ACD.

TREATMENT

Iron-Deficiency Anemia

The severity and cause of IDA determines the approach to treatment. Treatment is focused on replenishing iron stores. Because iron deficiency can be an early sign of other illnesses, treatment of the underlying disease may aid in the correction of iron deficiency.

DIETARY SUPPLEMENTATION AND ORAL IRON PREPARATIONS

Treatment of IDA usually consists of dietary supplementation and administration of oral iron preparations. Food high in iron are listed in Table 109–3. Iron is best absorbed from meat, fish, and poultry. These foods, as well as certain iron-fortified cereals can help with IDA. Orange juice and other ascorbic acid–rich foods can be included with meals to increase absorption. Milk and tea reduce absorption and should be consumed in moderation. In most cases of IDA, oral administration of iron therapy with soluble Fe^{2+} iron salts is appropriate.

CLINICAL CONTROVERSY

Daily ferrous sulfate is not tolerated by all patients and can be difficult to administer in populations of developing countries. Weekly rather than daily supplements have been used, with conflicting efficacy results. The weekly approach follows the natural pattern of mucosal cell turnover.

TABLE 109-3 Good Sources of Iron

Food	Serving Size	Amount (mg)
Total cereal	1 cup	18
Grape-Nuts cereal	1 cup	18
Instant Cream of Wheat	1 cup	8.2
Instant plain oatmeal	1 cup	6.7
Wheat germ	1 oz	2.6
Broccoli	1 medium stalk	2.1
Baked potato	1 medium	2.7
Raw tofu	½ cup	4
Lentils	½ cup	3.3
Beef chuck	3 oz	3.2

TABLE 109-4 Oral Iron Products

Salt	Elemental Iron Percentage	Elemental Iron Provided
Ferrous sulfate	20%	60–65 mg/324–325 mg tablet 18 mg iron/5 mL syrup 44 mg iron/5 mL elixir 15 mg iron/0.6 mL drop
Ferrous sulfate (exsiccated)	30%	65 mg/200 mg tablet 60 mg/187 mg tablet 50 mg/160 mg tablet
Ferrous gluconate	12%	36 mg/325 mg tablet 27 mg/240 mg tablet
Ferrous fumarate	33%	33 mg/100 mg tablet 63–66 mg/200 mg tablet 106 mg/324–325 mg tablet 15 mg/0.6 mL drop 33 mg/5 mL suspension
Polysaccharide iron complex	100%	150 mg capsule 50 mg tablet 100 mg/5 mL elixir
Carbonyl iron	100%	50 mg caplet

Fe^{2+} sulfate, succinate, lactate, fumarate, glycine sulfate, glutamate, and gluconate are absorbed similarly. The addition of copper, cobalt, molybdenum, or other minerals or hematinics provides no advantage but adds expense. The carbonyl iron may be advantageous because of lower risk for death in cases of accidental overdose. Iron is best absorbed in the reduced Fe^{2+} form, with maximal absorption occurring in the duodenum, primarily due to the acidic medium of the stomach. Slow-release or sustained-release iron preparations do not undergo sufficient dissolution until they reach the small intestine. In the alkaline environment of the small intestine, iron tends to form insoluble complexes, which significantly reduces absorption. The dose of iron replacement therapy depends on the patient's ability to tolerate the administered iron. Tolerance of iron salts improves with a small initial dose and gradual escalation to the full dose. For patients with IDA, the general recommendation is administration of approximately 200 mg of elemental iron daily, usually in two or three divided doses to maximize tolerability. If patients cannot tolerate this daily dose of elemental iron, smaller amounts of elemental iron (e.g., single 325 mg tablet of Fe^{2+} sulfate) usually is sufficient to replace iron stores, although at a slower rate. Table 109–4 lists the percentage of elemental iron of commonly available iron salts. The percentage of iron absorbed decreases progressively as the dose increases, although the absolute amount absorbed increases. Iron preferably is administered at least 1 hour before meals because food interferes with iron absorption. Many patients must take iron with food because they experience gastrointestinal upset when iron is administered on an empty stomach.

Adverse reactions to therapeutic doses of iron are primarily gastrointestinal in nature and consist of dark discoloration of feces, constipation or diarrhea, nausea, and vomiting. Gastrointestinal side effects usually are dose related and are similar among iron salts when equivalent amounts of elemental iron are administered. Administration of smaller amounts of iron with each dose may minimize these adverse effects. Histamine-2 blockers or proton pump inhibitors reduce gastric acidity and may impair iron absorption. Table 109–5 lists drug interactions with iron. Failure to develop at least some mild gastrointestinal symptoms may suggest nonadherence. If these side effects become intolerable, the total daily dose can be decreased or the dose can be taken with meals.

Failure to respond to appropriate treatment regimens necessitates reevaluation of the patient's condition. Occasionally a "therapeutic trial of iron" approach will be used to confirm a presumptive

TABLE 109-5 Iron Salt–Drug Interactions

Drugs That Decrease Iron Absorption	Object Drugs Affected by Iron
Al-, Mg-, and Ca^{+2}-containing antacids	Levodopa ↓ (chelates with iron)
Tetracycline and doxycycline	Methyldopa ↓ (decreases efficacy of methyldopa)
Histamine$_2$ antagonists	Levothyroxine ↓ (decreased efficacy of levothyroxine)
Proton pump inhibitors	Penicillamine ↓ (chelates with iron)
Cholestyramine	Fluoroquinolones ↓ (forms ferric ionquinolone complex)
	Tetracycline and doxycycline ↓ (when administered within 2 hours of iron salt)
	Mycophenolate ↓ (decreases absorption)

diagnosis of IDA. Common causes of treatment failure include poor patient adherence, inability to absorb iron, incorrect diagnosis, continued bleeding, or a concurrent condition that impairs full reticulocyte response. Even when iron deficiency is present, response may be impaired when a coexisting cause for anemia exists. Rarely a patient has diminished ability to absorb iron, most often due to previous gastrectomy, such as gastric bypass surgery, or celiac disease. Malabsorption can be ruled out by the iron test, in which plasma iron levels are determined at half-hour intervals for 2 hours following the administration of 50 mg of elemental iron as liquid Fe^{2+} sulfate. If plasma iron levels increase by >50 mcg/dL (>9.0 mol/L) during this time, absorption is satisfactory. Regardless of the form of oral therapy used, treatment should continue for 3 to 6 months after the anemia is resolved to allow for repletion of iron stores and to prevent relapse. Patients should be instructed to store oral iron out of reach of children and pets as small amounts can result in a fatal overdose. Products containing more than 30 mg of elemental iron are required to be packaged as individual dosage units to prevent toxicity. Treatment for acute iron poisoning is discussed in Chapter 14.

PARENTERAL IRON THERAPY

Indications for parenteral iron therapy include intolerance to oral, malabsorption, and long-term nonadherence. Patients with significant blood loss who refuse transfusions and can not take oral iron therapy also may require parenteral iron therapy. Parenteral iron therapy is also used for patients with chronic kidney disease (see Chap. 53), especially those undergoing hemodialysis, and for some cancer patients receiving chemotherapy on erythropoiesis stimulating agents (see Chap. 135). Four different parenteral iron preparations currently available in the United States are iron dextran, sodium ferric gluconate, iron sucrose, and ferumoxytol (Table 109–6). They differ in their molecular size, degradation kinetics, bioavailability, and side-effect profiles. Although toxicity profiles of these agents differ, clinical studies indicate that each is efficacious. Most of the recent research on intravenous iron has been performed in hemodialysis patients. Iron dextran parenteral preparations have been associated with death due to anaphylactic reactions. These reactions may be related to immune reactions to the iron–carbohydrate or iron–dextran complex. Another theory for the anaphylaxis is the high-molecular-weight dextran component, which may be antigenic even when not complexed to iron. The safety profile of parenteral iron is largely assessed by spontaneous reports to the Food and Drug Administration (FDA) and observational studies. All parenteral iron preparations carry a risk for anaphylactic reactions but likely to a lesser extent than iron dextran.[20,21] A concern with parenteral iron is that iron may be released

TABLE 109-6 Comparison of Parenteral Iron Preparations

	Ferumoxytol	Sodium Ferric Gluconate	Iron Dextran	Iron Sucrose
Amount of elemental iron	30mg/mL	62.5 mg iron/5 mL	50 mg iron/mL	20 mg iron/mL
Molecular weight	Feraheme: 75, 000 Da	Ferrlecit: 289,000–444,000 Da	InFeD: 165,000 Da DexFerrum: 267,000 Da	Venofer: 34,000–60,000 Da
Composition	Superparamagnetic iron oxide that is coated with a carbohydrate shell	Ferric oxide hydrate bonded to sucrose chelates with gluconate in a molar rate of 2 iron molecules to 1 gluconate molecule	Complex of ferric hydroxide and dextran	Complex of polynuclear iron hydroxide in sucrose
Preservative	None	Benzyl alcohol 9 mg/5 mL 20% (975 mg in 62.5 mg iron)	None	None
Indication	Treatment of iron deficiency anemia for adult patients with chronic kidney disease (CKD)	Treatment of iron-deficiency anemia for patients undergoing chronic hemodialysis who are receiving supplemental erythropoietin therapy	Treatment of patients with documented iron deficiency in whom oral therapy is unsatisfactory or impossible	Treatment of iron-deficiency anemia for patients undergoing chronic hemodialysis who are receiving supplemental epoetin alfa therapy
Warning	No black-box warning: hypersensitivity reactions	No black-box warning: hypersensitivity reactions	Black-box warning: anaphylactic-type reactions	Black-box warning: anaphylactic-type reactions
IM injection	No	No	Yes	No
Usual dose	Initial 510 mg intravenous injection followed by a second 510 mg intravenous injection 3 to 8 days later (rate 30 mg/s)	125 mg (10 mL) diluted in 100 mL normal saline, infused over 60 minutes; also can be administered as a slow IV injection (rate of 12.5 mg/min).	100 mg undiluted at a rate not to exceed 50 mg (1 mL) per minute	100 mg into the dialysis line at a rate of 1 mL (20 mg of iron) undiluted solution per minute
Treatment	2 doses × 510 mg = 1,020 mg	8 doses × 125 mg = 1,000 mg	10 doses × 100 mg = 1,000 mg	Up to 10 doses × 100 mg = 1,000 mg
Common adverse effects	Diarrhea, constipation, nausea, dizziness, hypotension, peripheral edema,	Cramps, nausea and vomiting, flushing, hypotension, rash, pruritus	Pain and brown staining at injection site, flushing, hypotension, fever, chills, myalgia, anaphylaxis	Leg cramps, hypotension

too quickly and overload the ability of transferrin to bind it, leading to free iron reactions that can interfere with neutrophil function. In regards to general estimation of total dose of parenteral iron needed to correct anemia, the following formula can be used:

Dose of iron (mg) =
whole blood hemoglobin deficit (g/dl) × body weight (lb)

An additional quantity of iron to replenish stores should be added. This is approximately 600 mg for women and 1,000 mg for men.[10]

Iron dextran, a complex of Fe^{3+} hydroxide and the carbohydrate dextran, contains 50 mg of iron per milliliter and can be given via the intramuscular or intravenous route. Different brands of iron dextran are available and differ in their molecular weight. They are not interchangeable. Iron dextran must be processed by macrophages for the iron to be biologically available. The absorption and metabolism vary with the route and amount of drug given. The intramuscular route is no longer used routinely.[22] The intramuscular administration of iron dextran requires Z-tract injection technique to minimize staining of the skin and pain. This technique is used for delivering intramuscular injections of irritating substances to minimize tracking of the medication through surrounding tissues. If intramuscular doses are given, they should not exceed 25 mg for patients weighing less than 5 kg, 50 mg for patients weighing less than 10 kg, and 100 mg for all other patients. Problems with intramuscular administration include patient discomfort, unpredictable delivery, sterile abscesses, tissue necrosis, and atrophy.[23]

The iron dextran package insert carries a black-box warning regarding the risk of anaphylaxis. A test dose is required prior to administration of any dose. Fatal reactions have also occurred in patients who tolerated the test dose. Patients with a history of multiple drug allergies and those who are concomitantly taking angiotensin-converting enzyme inhibitors may be at higher risk. Patients should also be monitored throughout the complete administration of iron dextran and resuscitative equipment should be readily available. Methods of intravenous administration include multiple slow injections of undiluted iron dextran solution or an infusion of a diluted preparation. This latter method often is referred to as total dose infusion.

Equations for calculating the appropriate doses of parenteral iron dextran for patients with IDA or anemia secondary to blood loss are listed in Table 109–7. Doses given by intravenous administration should not exceed 50 mg of iron per minute (1 mL/min). It is suggested that all patients considered for an iron dextran injection receive a test dose of 25 mg intramuscularly or intravenously or a 5- to 10-minute infusion of the diluted solution. Patients then should be observed for more than 1 hour for untoward reactions. An anaphylaxis-like reaction generally responds to intravenous epinephrine, diphenhydramine, and corticosteroids. If the test dose is tolerated, patients receiving total dose infusions can undergo infusion of the remaining solution during the next 2 to 6 hours.[23]

TABLE 109-7 Equations for Calculating Doses of Parenteral Iron Dextran

For patients with iron deficiency anemia:
Adults + children >15 kg
Dose (mL) = 0.0442 (Desired Hb − Observed Hb) × LBW + (0.26 × LBW)
LBW males = 50 kg + 2.3 × (inches over 5 ft)
LBW females = 45.5 kg + 2.3 × (inches over 5 ft)
Children 5–15 kg
Dose (mL) = 0.0442(Desired Hb − Observed Hb) × W + (0.26 × W)
For patients with anemia secondary to blood loss (hemorrhagic diathesis or long-term dialysis):
mg of iron = blood loss × hematocrit,
where blood loss is in milliliters and hematocrit is expressed as a decimal fraction.

Hb, hemoglobin; LBW, lean body weight; mL, milliliter; W, weight.

Total replacement doses of intravenous iron dextran have been given as a single dose. A test dose still is required. The ability to give a total dose infusion is a benefit of iron dextran over the other parenteral iron products.[17] Iron dextran is best utilized when smaller frequent doses of sodium ferric gluconate or iron sucrose are impractical. Patients who receive total dose infusions are at higher risk for adverse reactions, such as arthralgias, myalgias, flushing, malaise, and fever. Other adverse reactions of iron dextran include staining of the skin, pain at the injection site, allergic reactions, and rarely anaphylaxis. Patients with preexisting immune-mediated diseases, such as active rheumatoid arthritis or systemic lupus erythematosus, are considered at high risk for adverse reactions because of their hyperreactive immune response capabilities.

Sodium ferric gluconate is a complex of iron bound to one gluconate and four sucrose molecules in a repeating pattern. Its molecular weight is 289 kDa to 440 kDa. Sodium ferric gluconate is available in an aqueous solution. No direct transfer of iron from the Fe^{3+} gluconate to transferrin occurs. The complex is taken up quickly by the mononuclear phagocytic system and has a half-life of approximately 1 hour in the bloodstream. Sodium ferric gluconate appears to produce fewer anaphylactic reactions than iron dextran does. Side effects of sodium ferric gluconate include cramps, nausea, vomiting, flushing, hypotension, intense upper gastric pain, rash, and pruritus.[24]

Iron sucrose is a polynuclear iron (III) hydroxide in sucrose complex with a molecular weight of approximately 34 kDa to 60 kDa. It is available in 5 mL single-dose vials. Each vial contains 100 mg (20 mg/mL) of iron sucrose. Following intravenous administration of iron sucrose, the iron is released directly from the circulating iron sucrose to transferrin and is taken up by the mononuclear phagocytic system and metabolized. The half-life is approximately 6 hours, with a volume of distribution similar to that of iron dextran. Iron sucrose injection should not be administered concomitantly with oral iron preparations because it will reduce the absorption of oral iron.[25] Adverse effects include leg cramps and hypotension. Overall, iron sucrose has been shown to be safe and efficacious.

A fourth parenteral iron product, ferumoxytol, was approved in the United States in June 2009. Ferumoxytol is FDA approved to treat iron deficiency in adults with chronic kidney disease who are on or off diaylsis. The drug enters the macrophages in the liver, spleen, and bone marrow. The iron is then released and enters the storage pool as ferritin or is transported by transferrin for incorporation into Hb. Ferumoxytol can be administered at a quicker rate than other parenteral iron products with a rate up to 30 mg/s. Typical dosing is 510 mg intravenous dose followed by a second 510 mg dose 3 to 8 days later. The dose can be readministered after 1 month if anemia persists. No test dose is required but anaphylaxis can occur and patients should be observed for at least 30 minutes after each dose. Compared with oral iron replacement therapy, ferumoxytol has a higher incidence of hypotension and dizziness but less diarrhea, nausea, constipation, and peripheral edema. The clinical significance of this new preparation is yet to be determined as it just started being marketed.[26]

TRANSFUSIONS

Another treatment for IDA is blood transfusion. The decision to manage anemia with blood transfusions is based on the evaluation of risks and benefits. Transfusion of allogeneic blood is indicated in acute situations of blood loss when hemodynamic support is needed. Transfusions may also be necessary for patients with cardiac instability or when blood loss cannot be immediately alleviated.

Blood transfusion in chronic anemia can elevate Hb concentration in the short term but does not address the underlying disorder.

Evaluation of Therapeutic Outcomes

A positive response to a trial of oral iron therapy results in a modest reticulocytosis in a few days, with an increase in Hb around 2 weeks with continued rapid rise in Hb. As the Hb level approaches normal, the rate of increase slows progressively. A Hb response of <2 g/dL (<20 g/L; <1.24 mmol/L) over a 3-week period warrants further evaluation. Hb should reach a normal level after 2 months of therapy and often sooner.[10] If the patient does not develop reticulocytosis, reevaluation of the diagnosis or iron replacement therapy is necessary.

Iron therapy should continue for a period sufficient for complete restoration of iron stores. Serum ferritin concentrations should return to the normal range prior to discontinuation of iron. The time interval required to accomplish this goal varies, although at least 6 to 12 months of therapy usually is warranted. Patients with negative iron balances caused by bleeding may require iron replacement therapy for only 1 month after correction of the underlying lesion, whereas patients with recurrent negative balances may require long-term treatment with as little as 30 to 60 mg of elemental iron daily.

When large amounts of parenteral iron are administered, by either total dose infusion or multiple intramuscular or intravenous doses, the patient's iron status should be closely monitored. Patients receiving regular intravenous iron should be monitored for clinical or laboratory evidence of iron toxicity or overload. Iron overload may be indicated by abnormal hepatic function tests, serum ferritin >800 ng/mL (>800 g/L), or transferrin saturation >50%. Serum ferritin and transferrin saturation should be measured in the first week after doses of 100 to 200 mg and 2 weeks after larger intravenous iron doses. Hb and Hct should be measured weekly, and serum iron and ferritin levels should be measured at least monthly. Serum iron values can be obtained reliably 48 hours after intravenous dosing.

MEGALOBLASTIC ANEMIAS

Macrocytic anemias are divided into megaloblastic and nonmegaloblastic anemias. Macrocytosis, as seen in megaloblastic anemias, is caused by abnormal DNA metabolism resulting from vitamin B_{12} or folate deficiency. It also can be caused by administration of various drugs, such as hydroxyurea, zidovudine, cytarabine, methotrexate, azathioprine, 6-mercaptopurine, and cladribine. In vitamin B_{12}– or folate-deficiency anemia, megaloblastosis results from interference with folic acid– and vitamin B_{12}–interdependent nucleic acid synthesis in the immature erythrocyte. The rate of RNA and cytoplasm production exceeds the rate of DNA production. The maturation process is retarded, resulting in immature large RBCs (macrocytosis). RNA and DNA synthesis depend on a series of reactions catalyzed by vitamin B_{12} and folic acid because of their role in the conversion of uridine to thymidine. As shown in Fig. 109–5, dietary folates are absorbed in this process and converted to 5-methyl-tetrahydrofolate (A), which then is converted via a B_{12}-dependent reaction (B) to tetrahydrofolate (C). After gaining a carbon, tetrahydrofolate is converted to 5,10-methyl-tetrahydrofolate (D), a folate cofactor used by thymidylate synthetase (E) in the biosynthesis of nucleic acids. The 5,10-methyl-tetrahydrofolate cofactor is converted to dihydrofolate (F) during biosynthesis. Dihydrofolate reductase normally reduces dihydrofolate back to tetrahydrofolate (C), which can again pick up a carbon and be recycled to produce more 5,10-methyl-tetrahydrofolate (D).

Although vitamin B_{12} and folate deficiency are common causes of macrocytosis, other possible causes must be considered if these deficiencies are not found. Other causes of macrocytosis include

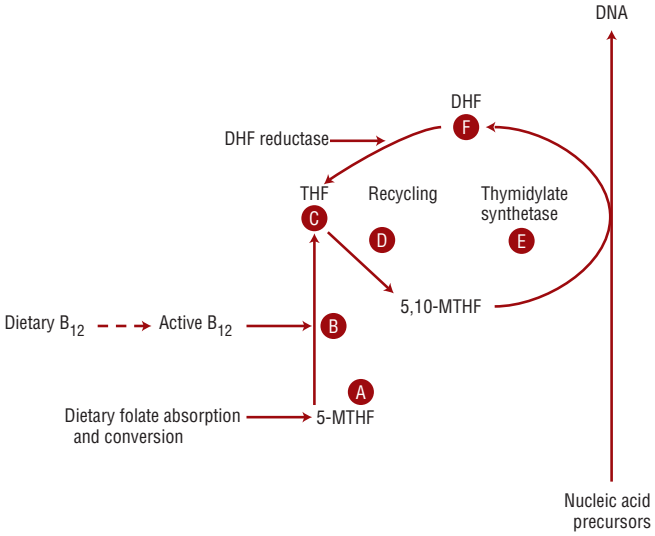

FIGURE 109-5. Drug-induced megaloblastosis (DHF, dihydrofolate; 5-MTHF, 5-methyl-tetrahydrofolate; 5,10-MTHF, 5,10-methyl-tetrahydrofolate THF; THF, tetrahydrofolate).

(1) a shift to immature or stressed RBCs as seen in reticulocytosis, aplastic anemia, and pure RBC aplasia; (2) a primary bone marrow disorder such as myelodysplastic syndromes, congenital dyserythropoietic anemias, and large granular lymphocyte leukemia; (3) lipid abnormalities as seen with liver disease, hypothyroidism, or hyperlipidemia; and (4) unknown mechanisms resulting from alcohol abuse and multiple myeloma. Macrocytosis is the most typical morphologic abnormality associated with excessive alcohol consumption. Even with adequate folate and vitamin B_{12} levels and the absence of liver disease, patients with high alcohol intake may present with an alcohol-induced macrocytosis. Cessation of alcohol ingestion results in resolution of the macrocytosis within a couple of months.

VITAMIN B_{12} DEFICIENCY ANEMIA

The prevalence of vitamin B_{12} deficiency causing anemia in the United States is unknown. Risk increases with age.[27] Increased use of gastric acid–suppressing agents, which may inhibit the release of cobalamin from food, is also associated with an increased risk. Older adults in the United States have a high prevalence (up to 15%) of elevated MMA levels and associated low or low–normal vitamin B_{12} levels, likely due to atrophic gastritis and malabsorption of food-bound vitamin B_{12}.[27]

Etiology

4 The three major causes of vitamin B_{12} deficiency are inadequate intake, malabsorption syndromes, and inadequate utilization. Inadequate dietary consumption of vitamin B_{12} is rare. It usually occurs only in patients who are strict vegans and their breast-fed infants, chronic alcoholics, and elderly patients who consume a "tea and toast" diet because of financial limitations or poor dentition. Decreased vitamin B_{12} absorption is seen in patients with pernicious anemia, which is caused by the absence of intrinsic factor due to autoimmune destruction of the gastric parietal cells, atrophy of the gastric mucosa, or stomach surgery. One of the most frequent causes of low serum B_{12} levels is malabsorption, which results from the inability of vitamin B_{12} to be cleaved and released from proteins in food because of inadequate gastric acid production. In these individuals, supplemental cobalamin is well absorbed because it is not protein bound. Treatment

of Helicobacter pylori may improve vitamin B_{12} status because this bacterial infection is a cause of chronic gastritis.[28] Vitamin B_{12} deficiency may result from overgrowth of bacteria in the bowel that use vitamin B_{12} or from injury or removal of ileal receptor sites where vitamin B_{12} and the intrinsic factor complex are absorbed. Blind loop syndrome, Whipple disease, Zollinger-Ellison syndrome, tapeworm infestations, intestinal resections, tropical sprue, surgical resection of the ileus, pancreatic insufficiency, inflammatory bowel disease, advanced liver disease, tuberculosis, and Crohn disease all may contribute to the development of vitamin B_{12} deficiency.[27]

Pathophysiology

Vitamin B_{12} works closely with folate in the synthesis of building blocks for DNA and RNA, is essential in maintaining the integrity of the neurologic system, and plays a role in fatty acid biosynthesis and energy production. It is a water-soluble vitamin obtained exogenously by ingestion of meat, fish, poultry, dairy products, and fortified cereals. The body stores several years of vitamin B_{12}, of which approximately one half is in the liver. The recommended daily allowance is 2 mcg in adults and 2.6 mcg in pregnant or breast-feeding women. The average western diet provides 5 to 15 mcg of vitamin B_{12} daily, of which 1 to 5 mcg is absorbed.[27] Vitamin B_{12} deficiency takes several years to develop following vitamin deprivation because of efficient enterohepatic circulation and stores of the vitamin.

Once dietary cobalamin enters the stomach, pepsin and hydrochloric acid release the cobalamin from animal proteins. The free cobalamin then binds to R-protein, which is released from parietal and salivary cells. In the duodenum, the cobalamin–R-protein is degraded, releasing free cobalamin. The cobalamin then binds with intrinsic factor that serves as a cell-directed carrier protein similar to transferrin for iron. This complex attaches to mucosal cell receptors in the distal ileum, the intrinsic factor is discarded, and the cobalamin is bound to transport proteins (transcobalamin I, II, and III). The cobalamin bound to transcobalamin II is secreted into the circulation and is taken up by the liver, bone marrow, and other cells. Most circulating cobalamin is bound to transcobalamin I and transcobalamin III. An alternate pathway for vitamin B_{12} absorption independent of intrinsic factor or an intact terminal ileum accounts for a small amount of vitamin B_{12} absorption.[27] This alternate pathway involves passive diffusion and accounts for approximately 1% absorption of the ingested vitamin B_{12}.

Vitamin B_{12} deficiency can also cause neurologic complications. These usually start with bilateral paraesthesia in extremities; deficits in proprioception and vibration can also be present. If not treated, this can progress to ataxia, dementia-like symptoms, and psychotic symptoms. In children prolonged deficiency can lead to poor brain development.[14,29] Patients with unexplained neuropathies should be evaluated for vitamin B_{12} deficiency.

Laboratory Findings

In macrocytic anemias, MCV usually is elevated >100 fL, but some patients deficient in vitamin B_{12} may have a normal MCV. If there is a coexisting cause of microcytosis, the MCV may not be elevated.[29] Mild leukopenia and thrombocytopenia are often present because abnormal DNA synthesis can affect all blood cells. A peripheral blood smear demonstrates macrocytosis accompanied by hypersegmented polymorphonuclear leukocytes (one of the earliest and most specific indications of this disease), oval macrocytes, anisocytosis, and poikilocytosis. Serum lactate dehydrogenase and indirect bilirubin levels may be elevated as a result of hemolysis or ineffective erythropoiesis.[14] Other laboratory findings include a low reticulocyte count, low serum vitamin B_{12} level [<150 pg/mL <111 pmol/L], and low Hct.

In the early stages of vitamin B_{12} deficiency, classic signs and symptoms of megaloblastic anemia may not be evident, and serum levels of vitamin B_{12} may be within normal limits. Therefore, measurement of MMA and homocysteine may be useful because these parameters are often the first to change. Because MMA and homocysteine are involved in enzymatic reactions that depend on vitamin B_{12}, a deficiency in vitamin B_{12} leads to accumulation of serum MMA and homocysteine. Elevations in MMA are more specific for vitamin B_{12} deficiency. Homocysteine is also elevated in several other situations including: folate deficiency, chronic renal disease, alcoholism, smoking, use of steroid or cyclosporine therapy, and smoking.[29] Low levels of vitamin B_{12} result in hyperhomocysteinemia, which some studies have reported to be an independent risk factor for cerebrovascular, peripheral vascular, coronary, and venous thromboembolic disease.[30]

Blood levels of vitamin B_{12} should be drawn for all patients with suspected vitamin B_{12} deficiency. Vitamin B_{12} values <150 pg/mL (<111 pmol/L) for patients with macrocytosis, hypersegmented polymorphonuclear leukocytes, peripheral neuropathy, or dementia are suggestive of B_{12} deficiency. Approximately one third of patients with pernicious anemia do not demonstrate macrocytosis if their condition is complicated by iron deficiency, thalassemia. Some patients with a clinical B_{12} deficiency with neurological involvement may have normal hematological parameters.

A Schilling test may be performed to diagnose pernicious anemia, but the usefulness of this test is questionable and rarely alters the clinical management of the vitamin B_{12} deficiency. The Schilling test was once performed to determine whether replacement of vitamin B_{12} should occur via an oral or parenteral route, but evidence now shows that oral replacement is as efficacious as parenteral supplementation because of the vitamin B_{12} absorption pathway independent of intrinsic factor.[27,31]

Other potentially useful tests include antibody testing and serum gastrin levels. Positive antiintrinsic factor antibodies may be present in approximately half of patients with pernicious anemia but is highly specific for the disease.[13] In addition, an estimated 85% of patients have antiparietal cell antibodies, but this test is not specific because 3% to 10% of healthy patients have these antibodies.[13] When evaluating low serum vitamin B_{12} levels, other causes besides dietary deprivation and malabsorption should be ruled out. For example, levels may be falsely low for patients receiving antibiotics, anticonvulsants, cytotoxic agents, oral contraceptives, and high-dose vitamin C.

TREATMENT

Vitamin B_{12} Deficiency Anemia

The goals of treatment for vitamin B_{12} deficiency include reversal of hematologic manifestations, replacement of body stores, and prevention or resolution of neurologic manifestations. Early treatment is of paramount importance because neurologic damage may be irreversible if the deficiency is not detected and corrected within months. In addition to replacement therapy, any underlying etiology that is treatable, such as bacterial overgrowth, should be remedied. Indications for starting oral or parenteral therapy include megaloblastic anemia or other hematologic abnormalities and neurologic disease from deficiency.[29] Those with borderline low levels of B_{12} but no hematologic abnormalities should be followed at yearly intervals.[29] Patients should be counseled on

TABLE 109-8 Good Sources of Vitamin B_{12}

Food	Serving Size	Amount (mcg)
Beef liver, cooked	3 oz	60
Breakfast cereal, fortified (100%)	¾ cup	6
Rainbow trout, cooked	3 oz	5.3
Sockeye salmon, cooked	3 oz	4.9
Beef, cooked	3 oz	2.1
Breakfast cereal, fortified (25%)	¾ cup	1.5
Haddock, cooked	3 oz	1.2
Clams, breaded and fried	¾ cup	1.1
Oysters, breaded and fried	6 pieces	1
Tuna, canned in water	3 oz	0.9
Milk	1 cup	0.9
Yogurt	8 oz	0.9

the types of foods high in vitamin B_{12} content such as fortified cereals as seen in Table 109–8. Orally administered vitamin B_{12} can be used effectively to treat pernicious anemia because of the aforementioned alternate pathway of passive absorption, independent of intrinsic factor.[14] Daily oral doses (1–2 mg) of vitamin B_{12} is as effective as intramuscular administration in achieving hematologic and neurologic responses.[27,31] If vitamin B_{12} levels are marginally low and either MMA or both MMA and homocysteine levels are elevated, administration of 1 mg of oral vitamin B_{12} daily should be strongly considered.[32] Timed-release preparations of oral cobalamin should be avoided.[33] Nonprescription 1 mg cobalamin tablets are available, among several other strengths. A commonly used initial parenteral vitamin B_{12} regimen consists of daily injections of 1,000 mcg of cyanocobalamin for 1 week to saturate vitamin B_{12} stores in the body and resolve clinical manifestations of the deficiency. Thereafter, it can be given weekly for 1 month and monthly thereafter for maintenance. Hydroxocobalamin is a less popular formulation of parenteral vitamin B_{12}. Its low utilization rate may be due to the occasional development of antibodies to the hydroxocobalamin–transcobalamin II complex. Parenteral therapy is preferred for patients exhibiting neurologic symptoms until resolution of symptoms and hematologic indices because the most rapid-acting therapy is necessary.[34] When patients are converted from the parenteral to the oral form of cobalamin, 1 mg of oral cobalamin daily can be initiated on the due date of the next injection.

In addition to the oral and parenteral forms, vitamin B_{12} is available as a nasal spray for patients in remission following intramuscular vitamin B_{12} therapy who have no nervous system involvement. The nasal spray is administered once weekly. Intranasal administration should be avoided for patients with nasal diseases or those receiving medications intranasally in the same nostril. Patients should not administer the spray 1 hour before or after ingestion of hot foods or beverages, which can impair cobalamin absorption. The efficacy of the nasal spray formulation has not been well studied, and it should be used for maintenance therapy only after hematologic parameters have normalized.

Potential adverse effects with vitamin B_{12} replacement therapy are rare. Uncommon side effects include hyperuricemia and hypokalemia due to marked increase in potassium utilization during production of new hematopoietic cells. Rebound thrombocytosis may precipitate thrombotic events. Another side effect of vitamin B_{12} therapy is fluid retention, which is more likely to occur for patients with compromised cardiovascular status because of an expansion in intravascular volume secondary to the sudden increase in production of RBCs. Rare cases of anaphylaxis with parenteral administration of cobalamin have been reported.

Evaluation of Therapeutic Outcomes

Most patients respond rapidly to vitamin B_{12} therapy. The typical patient will experience an improvement in strength and well-being within a few days. Bone marrow begins to become normoblastic in 2 to 3 days. Reticulocytosis is evident in 3 to 5 days. Hb begins to rise after the first week and should normalize in 1 to 2 months. CBC count and serum cobalamin levels usually are drawn 1 to 2 months after initiation of therapy and 3 to 6 months thereafter for surveillance monitoring. Homocysteine and MMA levels should be repeated 2 to 3 months after initiation of replacement therapy to evaluate for normalization of levels, although levels begin to decrease in 1 to 2 weeks. Neuropsychiatric signs and symptoms can be reversible if treated early. If permanent neurologic damage has resulted, progression should cease with replacement therapy. Slow response to therapy or failure to observe normalization of laboratory results may suggest the presence of an additional abnormality such as iron deficiency, thalassemia trait, infection, malignancy, nonadherence, or misdiagnosis.

FOLIC ACID DEFICIENCY ANEMIA

Epidemiology

Folic acid deficiency is one of the most common vitamin deficiencies occurring in the United States, largely because of its association with excessive alcohol intake and pregnancy.

Etiology

5 Major causes of folic acid deficiency include inadequate intake, decreased absorption, and increased folate requirements. Poor eating habits make this deficiency more common for elderly patients, teenagers whose diets consist of "junk food," alcoholics, food faddists, the impoverished, and those who are chronically ill or demented. Folic acid absorption may decrease for patients who have malabsorption syndromes or those who have received certain drugs. In alcoholics with poor dietary habits, alcohol interferes with folic acid absorption, interferes with folic acid utilization at the cellular level, and decreases hepatic stores of folic acid.

Increased folate requirements may occur when the rate of cellular division is increased, as seen in pregnant women; patients with hemolytic anemia, myelofibrosis, malignancy, chronic inflammatory disorders such as Crohn disease, rheumatoid arthritis, or psoriasis; patients undergoing long-term dialysis; burn patients; and for adolescents and infants during their growth spurts. This hyperutilization eventually can lead to anemia, particularly when the daily intake of folate is borderline, resulting in inadequate replacement of folate stores.

Several drugs have been reported to cause a folic acid deficiency megaloblastic anemia. Some drugs (e.g., azathioprine, 6-mercaptopurine, 5-fluorouracil, hydroxyurea, and zidovudine) directly inhibit DNA synthesis. Other drugs are folate antagonists; the most toxic is methotrexate (other examples include pentamidine, trimethoprim, and triamterene). A number of drugs (e.g., phenytoin, phenobarbital, and primidone) antagonize folate via poorly understood mechanisms but are thought to reduce vitamin absorption by the intestine (see Chap. 112). Since folic acid doses as low as 1 mg/day may affect serum phenytoin levels, routine folic acid supplementation is not generally recommended. The decline in phenytoin concentration usually occurs within the first 10 days and may decrease phenytoin levels by 15% to 50%.[35]

Pathophysiology

Folic acid is a water-soluble vitamin readily destroyed by cooking or processing. It is necessary for the production of nucleic acids,

proteins, amino acids, purines, and thymine and hence DNA and RNA. It acts as a methyl donor to form methylcobalamin, which is used in the remethylation of homocysteine to methionine. Because humans are unable to synthesize sufficient folate to meet total daily requirements, they depend on dietary sources. Major dietary sources of folate include fresh, green leafy vegetables, citrus fruits, yeast, mushrooms, dairy products, and animal organs such as liver and kidney. Most folate in food is present in the polyglutamate form, which must be broken down into the monoglutamate form prior to absorption in the small intestine. Once absorbed, dietary folate must be converted to the active form tetrahydrofolate through a cobalamin-dependent reaction. In 1997, the U.S. government mandated the fortification of grain products with folic acid in an attempt to increase the dietary intake of folate by 100 mcg of folate daily per person. This amount of supplementation was chosen to decrease the incidence of neural tube defects without masking occult vitamin B_{12} deficiency.

As a result of grain product fortification, neural tube defect frequency has decreased by 25% to 30%.[36] Although body demands for folate are high because of high rates of RBC synthesis and turnover, the minimum daily requirement is 50 to 100 mcg. In the general population, the recommended daily allowance for folate is 400 mcg in nonpregnant females, 600 mcg for pregnant females, and 500 mcg for lactating females.[36] Because the body stores approximately 5 to 10 mg of folate, primarily in the liver, cessation of dietary folate intake can result in megaloblastosis within 3 to 4 months. Folate is distributed to the other tissues primarily via enterohepatic recirculation. The methylated form of folate is reabsorbed from the bile into the serum. As folate enters the tissues, including erythrocytes, it endures for the remaining life span of the cell.

Laboratory Findings

It is of paramount importance to rule out vitamin B_{12} deficiency when folate deficiency is suspected. Laboratory changes associated with folate deficiency are similar to those seen in vitamin B_{12} deficiency, except vitamin B_{12} levels are normal. Serum folate levels decrease to less than 3 ng/mL (7 nmol/L) within a few days of reduced dietary folate intake. The RBC folate level (<150 ng/mL [<340 nmol/L]) also declines, and levels remain constant throughout the life span of the erythrocyte. An estimated 60% of patients with pernicious anemia have low RBC folate levels, probably because of the cobalamin requirement for normal transfer of methyl-tetrahydrofolate from plasma to cells.[13] If serum or erythrocyte folate levels are borderline, serum homocysteine usually is increased with a folic acid deficiency. If serum MMA levels also are elevated, vitamin B_{12} deficiency must be ruled out given that folate does not participate in MMA metabolism.

TREATMENT

Folic Acid Deficiency Anemia

Therapy for folic acid deficiency consists of administration of exogenous folic acid to induce hematologic remission, replace body stores, and resolve signs and symptoms. In most cases, 1 mg daily is sufficient to replace stores, except in cases of deficiency due to malabsorption, in which case doses of 1 to 5 mg daily may be necessary. Parenteral folic acid is available but rarely necessary. Synthetic folic acid is almost completely absorbed by the gastrointestinal tract and is converted to tetrahydrofolate without cobalamin. Therapy should continue for approximately 4 months if the underlying cause of the deficiency can be identified and corrected to allow for clearance of all folate-deficient RBCs from the circulation. Foods high in folic acid should also be encouraged in the diet as seen in Table 109–9. Long-term folate administration may be necessary in chronic conditions associated with increased folate requirements. Low-dose folate therapy (500 mcg daily) can be administered when anticonvulsant drugs produce a megaloblastic anemia so that discontinuation of anticonvulsant therapy may not be necessary. Adverse effects have not been reported with folic acid doses used for replacement therapy. It is considered nontoxic at high doses and is rapidly excreted in the urine.

TABLE 109-9 Good Sources of Folate

Food	Serving	Amount (mcg)
Chicken liver	3.5 oz	770
Cereal	½ to 1½ cups	100–400
Lentils, cooked	½ cup	180
Chickpeas	½ cup	141
Asparagus	½ cup	132
Spinach, cooked	½ cup	131
Black beans	½ cup	128
Pasta	2 oz	100–120
Kidney beans	½ cup	115
Lima beans	½ cup	78
White rice, cooked	¾ cup	60
Tomato juice	1 cup	48
Brussels sprouts	½ cup	47
Orange	1 medium	47

Although megaloblastic anemia during pregnancy is rare, the most common cause is folate deficiency. The condition usually manifests as an underweight premature infant and suboptimal health of the mother. Periconceptional folic acid supplementation is recommended to decrease the occurrence and recurrence of neural tube defects, specifically anencephaly and spinal bifida. Folic acid supplementation at a dose of 400 mcg daily is recommended for all women. Women who have previously given birth to offspring with neural tube defects or those with a family history of neural tube defects should ingest 4 mg daily of folic acid.[35,36,37] Higher levels of folic acid supplementation should not be attained via ingestion of excess multivitamins because of the risk for vitamin A toxicity.[37] Prenatal vitamins usually have a higher amount of folic acid as compared with general multivitamins to ensure adequate supplementation is attained. It is essential that women in their childbearing years maintain adequate folic acid intake.

Evaluation of Therapeutic Outcomes

Symptomatic improvement, as evidenced by increased alertness and appetite, often occur early during the course of treatment. Reticulocytosis begins in the first week. Hct begins to rise within 2 weeks and should reach normal levels within 2 months. MCV initially increases because of an increase in reticulocytes but gradually decreases to normal.

ANEMIA OF CHRONIC DISEASE

Epidemiology

6 ACD is one of the most common forms of anemia seen clinically, particularly among the elderly. It is especially important in the differential diagnosis of iron deficiency. ACD is associated with common disease states that may mimic the symptoms of anemia, which causes the diagnosis of ACD to sometimes be overlooked.

Etiology

The diagnosis of ACD usually is one of exclusion. It is important to exclude IDA as the true or competing etiology. Various

TABLE 109-10 Diseases Causing Anemia of Chronic Disease

Common causes
Chronic infections
Tuberculosis
Other chronic lung infections (e.g., lung abscess, bronchiectasis)
Human immunodeficiency virus
Subacute bacterial endocarditis
Osteomyelitis
Chronic urinary tract infections
Chronic inflammation
Rheumatoid arthritis
Systemic lupus erythematosus
Inflammatory bowel disease
Inflammatory osteoarthritis

Other (collagen vascular) diseases
Chronic inflammatory liver diseases
Malignancies
Carcinoma
Lymphoma
Leukemia
Multiple myeloma
Less common causes
Alcoholic liver disease
Congestive heart failure
Thrombophlebitis
Chronic obstructive pulmonary disease
Ischemic heart disease

conditions associated with ACD may predispose patients to blood loss [malignancy, gastrointestinal blood loss from treatments with aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), or corticosteroids]. ACD is often observed for patients with diseases that last longer than one to two months, although it can occur in conditions with a more rapid onset of several weeks, such as pneumonia. ACD tends to be a mild (Hb >9.5 g/dL [>95 g/L; >5.90 mmol/L]) or moderate (Hb >8 g/dL [80 g/L; >4.97 mmol/L]) anemia.[38] Anemia associated with human immunodeficiency virus (HIV), autoimmune conditions, cancer, and heart failure are common forms of ACD. A 1 g/dL (10 g/L; 0.62 mmol/L) decrease in Hb was independently associated with significantly increased mortality risk in several studies of the heart failure population.[39] The degree of anemia in ACD is generally associated with the severity of underlying disease. Table 109–10 lists common diseases associated with ACD.

ACD commonly develops in AIDS patients, especially those with opportunistic infections or malnutrition, and is associated with increased morbidity and mortality. For patients with HIV, anemia is a predictor of progression to AIDS and is independently associated with an increased risk of death.[40] The etiology of anemia for patients with HIV is complex. HIV infects hematopoietic cells, which can lead to abnormal hematopoiesis and bone marrow suppression. In addition, the drugs used to treat AIDS and associated illness can cause bone marrow suppression.

Pathophysiology

ACD is a response to stimulation of the cellular immune system by various underlying disease processes. ACD is a hypoproliferative anemia that traditionally has been associated with infectious or inflammatory processes, tissue injury, and conditions associated with release of proinflammatory cytokines. Alternative names include anemia of inflammation and cytokine-mediated anemia. The pathogenesis of ACD is multifactorial and is characterized by a blunted EPO response to anemia, an impaired proliferation of erythroid progenitor cells, and a disturbance of iron homeostasis.

TABLE 109-11 Laboratory Value Differences Between Anemia of Chronic Disease and Iron-Deficiency Anemia

	Anemia of Chronic Disease	Iron-Deficiency Anemia	Both
Iron	↓	↓	↓
Transferrin	↓or nl	↓	↓
Transferrin saturation	↓	↓	↓
Ferritin	↑or nl	↓	↓or nl
Soluble transferrin receptor	nl	↑	↑or nl

nl, normal limits.

Increased iron uptake and retention occur within cells of the mononuclear phagocytic system. The RBCs have a shortened life span, and the bone marrow's capacity to respond to EPO is inadequate to maintain normal Hb concentration. The cause of this defect is uncertain but appears to involve blocked release of iron from cells in the bone marrow. Iron availability to erythroid progenitor cells then is limited. Various cytokines, such as interleukin-1, interferon-γ, and tumor necrosis factor released during illness may inhibit the production or action of EPO or the production of RBCs.[38] Hepcidin may decrease duodenal absorption of iron and block release of iron from macrophages.[38]

Laboratory Findings

No definitive test can confirm the diagnosis of ACD. The practitioner should maintain a high index of suspicion for any patient with a chronic inflammatory or neoplastic disease. ACD may coexist with IDA and folic acid deficiency because many patients with these conditions have poor dietary intake or gastrointestinal blood loss. Examination of the bone marrow reveals an abundance of iron, suggesting that the release mechanism for iron is the central defect. Patients with ACD usually have a decreased serum iron level, but unlike patients with IDA, their serum ferritin level is normal or increased and their TIBC is decreased. Transferrin saturation is typically decreased. ACD usually is normocytic and normochromic with mildly depressed Hb. With ACD, hypochromia usually precedes microcytosis, with the opposite finding in IDA. Patients with concurrent ACD and IDA usually have microcytes and a more severe anemia. Table 109–11 shows lab values seen in ACD and IDA. Erythrocyte survival may be reduced for patients with ACD, but a compensatory erythropoietic response usually does not occur. A low reticulocyte count indicates underproduction of red cells.[38]

TREATMENT

Anemia of Chronic Disease

Treatment of ACD depends on the underlying etiology. Guidelines exist for management of anemia for patients with cancer or chronic kidney disease (see Chaps. 53 and 135). Although the goals of therapy should include treating the underlying disorder and correcting reversible causes of anemia, accomplishment of these goals may not totally reverse hematologic and physiologic abnormalities. Iron is effective only if iron deficiency is present. During inflammation, oral or parenteral iron therapy is not as effective. Absorption is impaired because of downregulation of ferroportin and iron diversion mediated by cytokines.[38] Because iron is a required nutrient for proliferating microorganisms, supplementation may theoretically increase the risk of infections. Iron therapy should be reserved for those patients with an absolute iron deficiency.[38]

RBC transfusions are effective but should be limited to situations in which oxygen transport is inadequate due to concomitant medical problems. Transfusions are typically considered for those with severe anemia (Hb <8 g/dL [<80 g/L; <4.97 mmol/L]) but can be considered for those between 8 to 10 g/dL (80 to 100 g/L; 4.97 to 6.21 g/L) based on factors such as cost, convenience, and risk of complications. Risks may include transmission of bloodborne infections, development of autoantibodies, transfusion reactions, and iron overload. Transfusion is of doubtful benefit for patients with Hb >8 g/dL (>80 g/L; >4.97 mmol/L) if they are not symptomatic with anemia.

Erythropoiesis-stimulating agents (ESAs) have been used to stimulate erythropoiesis for patients with ACD since a relative EPO deficiency exists for the degree of anemia. Two agents are available: recombinant epoetin alfa and recombinant darbepoetin alfa. Although both agents share the same mechanism of action, darbepoetin alfa has a longer half-life and can be administered less frequently. Although these agents are sometimes used to treat ACD, this is currently not an FDA-approved indication. Patients with chronic disease may have a relatively impaired response to ESAs. The initial dosage of epoetin alfa and darbepoetin alfa are typically 50 to 100 units per kilogram three times per week and 0.45 mcg per kilogram once weekly, respectively. These doses are typical starting doses for those with chronic kidney disease. Response to ESAs varies depending on dose and cause of the anemia. ESA treatment is effective when the marrow has an adequate supply of iron, cobalamin, and folic acid. Whether EPO levels are a useful predictor of response is controversial.

Iron deficiency can occur in patients treated with ESAs; so close monitoring of iron levels is necessary. Some patients develop "functional" iron deficiency, in which the iron stores are normal but the supply of iron to the erythroid marrow is less than necessary to support the demand for RBC production. Therefore, many practitioners routinely supplement ESA therapy with oral iron therapy. Potential toxicities of exogenous ESA administration include increases in blood pressure, nausea, headache, fever, bone pain, and fatigue. Less common adverse effects include seizures, thrombotic events, and allergic reactions such as rashes and local reactions at the injection site. If ESAs are used the practitioner must monitor to ensure the patient's Hb does not exceed 12 g/dL (120 g/L; 7.45 mmol/L) with treatment or that Hb does not rise >1 g/dL (>10 g/L; >0.62 mmol/L) every 2 weeks since both of these events have been associated with increased mortality and cardiovascular events.[41] Tumor progression with these agents can also occur and is discussed in Chap. 135. Further discussion of dosing guidelines and potential adverse outcomes of ESA treatment in populations for which treatment is FDA approved are discussed in Chaps. 53 and 135.

Evaluation of Therapeutic Outcomes

One of the earliest responses to increased endogenous or exogenous EPO is an increase in blood reticulocyte count, which usually occurs in the first few days. Baseline iron status should be checked before and during treatment, as many patients receiving ESAs require supplemental iron therapy. The optimal form and schedule of iron supplementation are not known. Hb levels should be monitored twice a week until stabilized. Hb should also be monitored twice weekly for 2 to 6 weeks after a dose adjustment.[41] A fall in Hb during ESA therapy may indicate a need for iron supplementation or signal occult blood loss. Baseline and periodic monitoring of iron, TIBC, transferrin saturation, or ferritin levels may be useful in optimizing iron repletion and limiting the need for ESAs. Patients who do not respond to 8 weeks of optimal dosage should not continue taking ESAs. Target Hb levels should be 11 to 12 g/dL (110 to 120 g/L; 6.83 to 7.45 mmol/L). Cost is an issue with ESA therapy; therefore, drug expense must be weighed against the effects on transfusions and hospitalizations.

ANEMIA OF CRITICAL ILLNESS

Epidemiology

❼ Anemia is a common complication in critically ill patients and is found almost universally in this patient population.[42] Approximately 95% of patients have less than normal Hb levels by their third day in the intensive care unit (ICU).[43]

Etiology

Factors that may contribute to anemia in critically ill patients include sepsis, taking of frequent blood samples, hemodilution, surgical blood loss, immune-mediated functional iron deficiency, decreased production of endogenous EPO, reduced RBC life span, and active bleeding, especially in the gastrointestinal tract. More commonly, a combination of these factors exists. Additional comorbid factors include coagulopathies and nutritional deficits such as malnourishment and altered absorption of vitamins and minerals, including iron, vitamin B_{12}, and folate.[44] Deleterious effects of anemia include an increased risk of cardiac-related morbidity and mortality, especially for patients with known cardiovascular disease. Persistent tissue hypoxia can result in cerebral ischemia, myocardial ischemia, multiple organ deterioration, lactic acidosis, and death. Consequences of anemia in critically ill patients may be enhanced because of the increased metabolic demands of critical illness. Weaning anemic patients from mechanical ventilation may be more difficult.[45]

Pathophysiology

In anemia of critical illness, the mechanism for RBC replenishment and homeostasis is altered. The effect of various inflammatory cytokines on EPO may partly explain anemia of critical illness because inflammatory cytokines are associated with a blunted erythropoietic response.[46] Inflammatory cytokines appear to directly inhibit RBC production and stimulate synthesis of iron-binding proteins that sequester iron and limit RBC production.[46]

Laboratory Findings

The pattern of laboratory findings in anemia of critical illness is similar to that of ACD. Laboratory findings frequently seen in anemia of critical illness are low serum iron, TIBC, and iron/TIBC ratio. Transferrin saturation usually is less than 20% in anemia of critical illness due to functional iron deficiency. Serum ferritin is normal to high, as seen with ACD, and EPO levels usually are slightly decreased despite the presence of anemia, with minimal reticulocyte response.[42,46] These findings differ from those for patients with IDA, who generally have elevated EPO concentrations in response to a low Hct.

TREATMENT

Anemia of Critical Illness

Patients with anemia of critical illness require the necessary substrates of iron, folic acid, and vitamin B_{12} for RBC production. Parenteral iron is generally preferred in this population because patients often are undergoing enteral therapy or because of concerns regarding inadequate iron absorption. The disadvantage of parenteral therapy is the theoretical risk of infection.

CLINICAL CONTROVERSY

The low iron concentrations in critically ill patients may be a defense mechanism, as microbes require iron for sustenance. Therefore, diminished iron levels may inhibit bacterial growth. Further investigation of supplementation with iron is warranted.

Pharmacologic doses of ESAs have been used to treat the anemia of critical illness. Few randomized controlled trials have evaluated the role of ESAs in critically ill patients, and the results of these trials have not consistently shown a decrease in transfusion requirements in ESA-treated patients.[46] Further investigation is necessary to determine the effectiveness and the cost effectiveness of ESAs in critically ill patients.[43]

Many critically ill patients receive RBC transfusions despite the inherent risks associated with transfusions. Stored RBCs may not function as well as endogenous blood. Although RBC transfusions may increase oxygen delivery to tissues, cellular oxygen may not increase.[47] Transfusion practices in ICUs vary, and clinicians use different Hb concentrations as thresholds for administering transfusions. Study results suggest that RBC transfusions may decrease the likelihood of survival in some subgroups of critically ill patients.[48] Decisions to use transfusions must consider the risks, including transmission of infections; volume overload, especially for patients with renal or heart failure; iron overload; and immune-mediated reactions such as febrile reactions, hemolysis, and anaphylaxis. The clinician also must consider administrative, logistic, and economic factors, including the shortage of blood supplies.

Evaluation of Therapeutic Outcomes

Goals of therapy include maintenance of adequate tissue oxygenation and perfusion and immediate correction of severe anemia. The role of monitoring RBCs, Hb, Hct, EPO levels, and reticulocyte counts remains to be determined. Outcomes used in ESA studies are transfusion requirements and transfusion independence. Morbidity, mortality, and length of stay also should be assessed. Iron lab studies should be monitored to ensure that adequate amounts of iron are present to support an optimal erythropoietic response to ESAs.

ANEMIA IN THE ELDERLY

Epidemiology

8 One of the most common clinical problems observed in the elderly is anemia. Anemia is a prevalent and increasing problem in the elderly, with approximately 20% of people 85 years and older affected.[49] Elderly patients with the highest incidence of anemia are those who are hospitalized, followed by residents of nursing homes and institutions, with an estimated rate of 31% to 40%.[50] The lowest incidence is seen in elderly patients who are community dwellers. Although the incidence of anemia is high in the elderly, anemia should not be regarded as an inevitable outcome of aging. The body's set point of hemoglobin does not fall with age. An underlying cause can be identified in approximately two thirds of older patients. Undiagnosed and untreated anemia has been associated with adverse outcomes, including all-cause hospitalization, hospitalization secondary to cardiovascular disease, and all-cause mortality.[51] Anemia is an independent predictor of death and major clinical adverse events in elderly patients with stable symptomatic coronary artery disease.[52] Anemia can exacerbate neurologic and cognitive conditions and can adversely influence quality of life and physical performance in the elderly.[53] Anemia may be an indication of serious diseases such as gastrointestinal cancer.

Pathophysiology

Aging is associated with a progressive reduction in hematopoietic reserve, which makes individuals more susceptible to developing anemia in times of hematopoietic stress.[54] Dysregulation of proinflammatory cytokines, most notably interleukin-6, may inhibit EPO production or interact with EPO receptors.[55] Although Hb levels may remain normal, the diminished marrow reserve leaves the elderly patient more susceptible to other causes of anemia. Renal insufficiency, which also is common in elderly patients, may reduce the ability of the kidneys to produce EPO. Older patients often have a normal creatinine level but a diminished glomerular filtration rate. Myelodysplastic syndromes are another common cause of anemia in the elderly, but most anemia cases in the elderly are multifactorial.

Etiology

In the acute care setting, the top three causes of anemia in the elderly are chronic disease (35%), unexplained cause (17%), and iron deficiency (15%), whereas in community-based outpatient clinics, the most common causes are unexplained (36%), infection (23%), and chronic disease (17%).[56] Risk factors for the development of anemia in the elderly include race and ethnicity. The highest prevalence is seen for elderly blacks, those with serum albumin and serum creatinine abnormalities, and patients with recent hospitalization or placement in an institution.[50]

Anemia in the elderly usually is typically hypoproliferative and reflects an inability of the aging hematopoietic system to replace the peripheral blood loss or respond to marrow insults. Unexplained causes may be due to inadequate diagnostic evaluation or absolute or relative EPO deficiency. Absolute EPO deficiency may be associated with renal insufficiency, whereas relative deficiency may be due to the body's inability to provide adequate response to declining Hb levels.[56]

Another common problem in the elderly is vitamin B_{12} deficiency. The most common causes of clinically overt vitamin B_{12} deficiency are food/cobalamin malabsorption (more than 60% of cases) and pernicious anemia (15% to 20% of cases).[57]

One often-overlooked major factor that may contribute to anemia in the older population is nutritional status. Cognitive and functional impairments in the older population may create barriers for patients to obtain and prepare a nutritious diet. Nutritional deficiencies that are not severe enough to affect the hematopoietic system in the younger population may contribute to anemia in the elderly. Edentulous or infirm elderly who may be too ill to prepare their meals are at risk for nutritional folate deficiency. Risk factors for inadequate folate intake in the elderly include low energy intake, inadequate consumption of fortified cereals, and failure to take a vitamin/mineral supplement.[58] However, unlike cobalamin levels, folate levels often increase rather than decline with age. High folic acid intake can occur if the elderly patient regularly uses a supplement and consumes fortified cereals.[58,59]

Other common anemias in the elderly include IDA and ACD. Bleeding with resultant iron deficiency in the elderly may be due to carcinoma, ulcer, atrophic gastritis, drug-induced gastritis, postmenopausal vaginal bleeding, or bleeding hemorrhoids. Elderly women have a much lower incidence of IDA compared with younger, menstruating women. Until proven otherwise, iron deficiency in the elderly should be considered a sign of chronic blood loss. Steps should be taken to rule out bleeding, especially from the gastrointestinal or female reproductive tract. ACD is more common in the elderly, as diseases that contribute to ACD such as

cancer, infection, and rheumatoid arthritis are more prevalent in this population.

Laboratory Findings

For practical purposes, it is best to use usual adult reference values and WHO criteria for laboratory tests in the elderly. Anemia in elderly persons usually is normocytic and mild, with Hb values ranging between 10 and 12 g/dL (100 to 120 g/L; 6.21 to 7.45 mmol/L) in most anemic patients.[49] Evaluation of an elderly patient should be similar to strategies described previously for younger adults, perhaps with more emphasis on identifying occult blood loss and vitamin B_{12} deficiency. Vitamin B_{12} deficiency may be present even when plasma levels of vitamin B_{12} are within the normal range, but elevated MMA levels will detect the deficiency. A refractory macrocytic anemia in the elderly should raise suspicion of a myelodysplastic syndrome.

TREATMENT

Anemia in the Elderly

Treatment of anemia in the elderly is the same as that described for each type of anemia discussed in this chapter. With IDA it is essential to treat the underlying cause, if known (i.e., bleeding), and administer iron supplementation. Lower doses of iron supplementation are often recommended in the elderly (e.g., 325 mg of ferrous sulfate once daily) to decrease the incidence of gastrointestinal adverse effects, which can lead to additional morbidity and poor adherence. The goal of treatment of ACD is resolution of the underlying cause, although curing the underlying chronic illness for elderly patients can be difficult. Routine treatment with ESAs is not currently standard of care for ACD in the elderly. The medical and economic implications of anemia correction remain to be defined for ACD or undefined anemia.

Evaluation of Therapeutic Outcomes

Responses and monitoring of treatment are similar in the elderly as described for the general adult population described earlier in the chapter. If the reticulocyte count rises but the anemia does not improve, inadequate absorption of iron or continued blood loss should be suspected. As with any form of anemia, symptomatic improvement should be evident shortly after starting therapy, and Hb/Hct should begin to rise within a few weeks of initiating therapy. A key component of symptom assessment among older adults is the functional domain. Patients should be asked about changes in self-care abilities, mobility, and stamina.

ANEMIA IN PEDIATRIC POPULATIONS

Epidemiology

9 IDA is a leading cause of infant morbidity and mortality around the world.[60] Data from NHANES III indicated that 9% of children ages 12 to 36 months in the United States had iron deficiency and 3% had IDA.[61,62] Lack of a normal Hb at birth directly affects nonstorage iron and increases the risk of IDA in the first 3 to 6 months of life. African- or Hispanic-American children have a higher incidence of anemia.[63] Requirements for iron absorption peak during puberty. An anemia of prematurity can occur 3 to 12 weeks after birth in infants younger than 32 weeks' gestation and spontaneously resolves by 3 to 6 months. The prevalence of vitamin B_{12} deficiency has been identified as 1 in 1,255 for levels <100 pg/mL (<74 pmol/L) and 1 in 200 for levels of <200 pg/mL (<148 pmol/L), with the lowest levels in non-Hispanic whites.[64]

Pathophysiology

In contrast to anemias in adults, which tend to be manifestations of a broader underlying pathology, anemias in the pediatric population are more often due to a primary hematologic abnormality. The amount of iron present at birth depends on gestational length and weight. Erythropoiesis normally decreases after birth. A concurrent decrease in EPO production results in a physiologic anemia at peaking at 2 months.[65] Iron stores are mostly depleted by age 6 months.

Etiology

The age of the child can yield some clues regarding the etiology of the anemia. The optimal amount of nutritional iron and folate required varies among individuals based on life-cycle stages. Two peak periods place children at risk of developing IDA. The first peak period occurs during late infancy and early childhood, when children undergo rapid body growth, have low levels of dietary iron, and exhaust stores accumulated during gestation. The second peak period occurs during adolescence, which is associated with rapid growth, poor diets, and onset of menses in girls. Some studies suggest that overweight children are at significantly higher risk for IDA. Proposed factors include genetic influences; physical inactivity, leading to decreased myoglobin breakdown and lower amounts of released iron into the blood; and inadequate diet with limited intake of iron-rich foods.[66]

Conditions in the newborn period that can lead to IDA include prematurity and insufficient dietary intake. Premature infants are at increased risk for IDA because of their smaller total blood volume, increased blood loss through phlebotomy, and poor gastrointestinal absorption. Blood loss and hemolysis are other common causes of anemia in neonates. Factors leading to unbalanced iron metabolism in infants include insufficient iron intake, decreased absorption, early introduction of cow's milk, intolerance of cow's milk, medications, and malabsorption. Dietary deficiency of iron in the first 6 to 12 months of life is less common today because of the increased use of iron supplementation during breast-feeding and use of iron-fortified formulas. Iron deficiency becomes more common when children change to regular diets.

When screening for iron deficiency in young children, a careful dietary history can help identify children at risk. High iron needs and the tendency to eat fewer iron-containing foods contribute to the etiology of iron deficiency during adolescence.

Other causes of microcytic anemia include thalassemia, lead poisoning, and sideroblastic anemia. Use of homeopathic or herbal medications and exposure to paint or certain cooking materials may place children at risk for lead exposure. Normocytic anemias in children include infection with human parvovirus B19 and glucose-6-phosphate dehydrogenase (G6PD) deficiency. Macrocytic anemias are caused by deficiencies in vitamin B_{12} and folate, chronic liver disease, hypothyroidism, and myelodysplastic disorders. Folic acid deficiency usually is due to inadequate dietary intake, but human milk and cow's milk provide adequate sources. Folic acid deficiency may be seen in infants and children who primarily consume goat's milk or health food milk alternatives, or in children with insufficient intake of green leafy vegetables. Vitamin B_{12} deficiency due to nutritional reasons is rare but may occur due to a congenital pernicious anemia.

Laboratory Findings

When evaluating laboratory values for pediatric patients, the clinician must use age- and sex-adjusted norms. It is important to know that many blood samples are capillary samples, such as heel or finger

sticks, which may have slightly different results than venous samples. The USPSTF has concluded that evidence is insufficient to recommend for or against routine screening for IDA in asymptomatic, low risk, children aged 6 to 12 months. The Hb is a sensitive test for iron deficiency, but it has low specificity in childhood anemias. If an abnormality is found, a CBC should be ordered to evaluate MCV and determine whether the anemia is microcytic, normocytic, or macrocytic. A peripheral blood smear and reticulocyte count also may be helpful. The peripheral blood smear can indicate the etiology based on RBC morphology, and the reticulocyte count helps differentiate between decreased RBC production and increased RBC destruction or loss. Other laboratory tests include serum iron, ferritin, TIBC, and transferrin saturation. Mild hereditary anemias may produce a mild hypochromic microcytic anemia that can be confused with IDAs. The RDW may be high with iron deficiency and is more likely to be normal with thalassemia. Laboratory features of anemia of prematurity include normocytic normochromic cells, low reticulocyte count, low serum EPO concentrations, and decreased RBC precursors in bone marrow. Laboratory diagnosis of vitamin B_{12} and folate deficiency in children is similar to that of adults.

TREATMENT

Anemia in Pediatric Populations

Primary prevention of IDA in infants, children, and adolescents is the most appropriate goal because delays in mental and motor development are potentially irreversible. In 2006, the USPSTF published revised recommendations to screen and supplement iron deficiency in the United States, focusing on children and pregnant women.[19] The USPSTF recommends routine iron supplementation for asymptomatic children aged 6 to 12 months who are at increased risk for IDA. Fair evidence was found that iron supplementation (e.g., iron-fortified formula or iron supplements) might improve neurodevelopmental outcomes in children at risk for IDA. Evidence of benefit for children 6 to 12 months of age not at risk for IDA was poor.

Interventions likely to prevent anemia include diverse foods with bioavailable forms of iron, food fortification for infants and children, and individual supplementation. Routine screening for iron deficiency in nonpregnant adolescents is recommended only for those with risk factors, which include vegetarian diets, malnutrition, low body weight, chronic illness, or history of heavy menstrual blood loss.

Anemia of prematurity is frequently treated with RBC transfusions, with wide variations in transfusion practices among neonatal ICUs. Reasons for transfusions include improved oxygen delivery, intravascular volume, reduced fatigue during feeding, and improved growth. ESAs have been used to treat anemia of prematurity, but it is important to note that ESA pharmacokinetics differ depending on the developmental age of the infant. ESA use is controversial because it has not been shown to clearly reduce transfusion requirements. Other questions regarding safety and proper use of ESAs in anemia of prematurity remain unanswered.

For infants aged 9 to 12 months with a mild microcytic anemia, the most cost-effective treatment is a therapeutic trial of iron. Fe^{2+} sulfate at a dose of 3 mg/kg of elemental iron once or twice daily between meals for 4 weeks is recommended. In children who respond, iron should be continued for 2 more months to replace storage iron pools, along with dietary intervention and patient education.[67] Parenteral iron therapy has a limited role and is rarely necessary.

For the macrocytic anemias in children, folate can be administered in a dose of 1 to 3 mg daily. However, vitamin B_{12} deficiency due to congenital pernicious anemia requires lifelong vitamin B_{12} supplementation. Dose and frequency should be titrated according to clinical response and laboratory values. No data regarding the use of oral vitamin B_{12} supplementation in children are available.

Evaluation of Therapeutic Outcomes

Therapeutic outcomes are assessed in children by monitoring Hb, Hct, and RBC indices 6 to 8 weeks after initiation of iron therapy. For premature infants, Hb or Hct should be monitored weekly.

HEMOLYTIC ANEMIA

Pathophysiology

⑩ Hemolytic anemia results from decreased survival time of RBCs secondary to destruction in the spleen or circulation. The severity of hemolytic anemia varies with the mechanism. Hemolysis may be mild, chronic, and compensated or acute, severe, and life threatening.

The normal 120-day life span of a RBC depends upon its inherent flexibility in passing through the microvasculature and spleen without disruption of the cell membrane or sequestration and phagocytosis by the mononuclear phagocytic system. Hemolysis, as defined by an RBC life span of less than 120 days, results from one of three primary defects that are intrinsic or extrinsic in origin: membrane defects, alterations in Hb solubility or stability, and changes in intracellular metabolic processes. Intrinsic defects are intracorpuscular changes and often are genetically determined. Extrinsic defects, or extracorpuscular changes, usually are the cause of acquired hemolytic anemia. Acquired disorders result mainly from a direct effect on the membrane and less often from alterations in Hb or metabolism. Table 109–12 lists examples of the different classes of hemolytic anemias.

Causes of hemolytic anemia in younger patients differ from causes in elderly patients. Most younger patients exhibit congenital disease, while older patients most often experience autoimmune hemolytic anemia. A positive Coombs test is diagnostic in the latter group.

Alterations in Hb solubility or stability, as seen with sickle cell anemia and the thalassemias, cause cell deformations leading to hemolysis (see Chap. 111).

Finally, alterations in cell metabolism (enzymopathies) lead to hemolytic disease by changing cell dimensions and Hb solubility.

The most common metabolic abnormality resulting in a hemolytic syndrome is G6PD deficiency in the hexose monophosphate shunt pathway described in Chap. 112. The disease more typically occurs in those of Mediterranean descent upon exposure to oxidant drugs (e.g., sulfamethoxazole and dapsone) and chemicals or with infection. Some drugs and ingested toxins (e.g., nitrofurantoin, cancer chemotherapy agents, phenazopyridine, sulfones, amyl nitrate, mothballs, paraquat, and hydrogen peroxide) can cause direct oxidative damage to erythrocytes (see Chap. 112).

TABLE 109-12 Common Classes of Hemolytic Anemias

Intrinsic (intracorpuscular; usually genetically inherited)
Membrane defect
Spherocytosis and elliptocytosis
Hemoglobin defect
Sickle cell anemia
Thalassemia syndrome
Metabolic defect
Glucose-6-phosphate dehydrogenase (G6PD) deficiency
Many other enzyme deficiencies
Extrinsic
Membrane defect
Autoimmune hemolytic anemias
Oxidants; may cause unstable hemoglobin to clump

Laboratory Findings

The appearance of RBCs varies greatly depending on the cause of the hemolytic anemia. An increased reticulocyte count is evidence of an attempt to maintain RBC mass. Depending on the disease, a peripheral blood smear may reveal sickle cells, target cells, spherocytes, elliptocytes, or fragmented RBCs. Decreased haptoglobin is seen, caused by increased Hb–haptoglobin complex formation. Lactate dehydrogenase level often is elevated secondary to release from RBCs, but this enzyme is very nonspecific. Hemoglobinuria may result, and an increase in indirect bilirubin often occurs.

TREATMENT

Hemolytic Anemia

Therapy for hemolytic anemia consists of managing the underlying cause of the anemia. Patients with G6PD deficiency should avoid use of precipitating oxidant medications and chemicals. No specific therapy compensates for this enzyme deficiency. Steroids and other immunosuppressive agents have been used for management of autoimmune hemolytic anemias. A splenectomy is sometimes indicated in an attempt to reduce RBC destruction.

PHARMACOECONOMIC CONSIDERATIONS

Anemia has an independent impact on many clinical, functional, and economic indicators, and evidence suggests that treatment can improve patient outcomes. The implications of treating anemia are becoming increasingly recognized, especially for the elderly. The cost of the complications associated with anemia in the elderly is considerable because anemia has been associated with an increased risk of falls, dementia, depression, and general functional disability that increases the demand for long-term care services.[68] However, the causal link between anemia and the costs of these conditions is not well established. Studies show that treatment of anemia in elderly patients with renal failure and heart failure is beneficial.[69] More research is needed to assess the costs and benefits of anemia therapies in other conditions, especially when treatment of mild anemia is considered.[69]

Although the direct medical costs of anemia are unknown, the direct costs of drug treatment must be weighed against the indirect costs associated with anemia.[70] The costs of laboratory tests used to diagnose anemia, the role of screening for anemia, and the prevention of anemia are components that must be considered in the pharmacoeconomic analysis. Additionally, the frequency of blood transfusions must be considered because it impacts cost and therapeutic decision making for patients. Blood products are a scarce resource that also must be factored into decision making.

For IDA, intravenous iron is costly but may have superior bioavailability compared with oral preparations. In some individuals, the bioavailability advantage of parenteral iron over oral iron can be the difference in achieving a successful outcome. The benefits of using combination oral iron products designed to enhance absorption probably are not warranted.

With regard to vitamin B_{12} deficiency, the cost of oral cyanocobalamin tablets and intramuscular injections is inexpensive. However, the parenteral route has significant additional costs, including the cost of a physician or nurse's visit for the injection or the cost of a home health visit. Additionally, many elderly patients may have difficulties attending extra clinic appointments because of transportation difficulties. A 90-day supply of nonprescription 1 mg oral tablets can be purchased for a few dollars. The disadvantage of the nasal spray is its higher cost compared with the oral or parenteral route.

For ACD, ESA cost needs to be taken into consideration along with safety as it is expensive. The cost of intravenous iron is low compared with the cost of ESAs. Because most patients with ACD are not symptomatic, they may feel no improvement with therapy. Symptom severity should be considered in the decision to use ESAs. Transfusion use for treatment of ACD as an alternative to ESAs must consider cost, convenience, and risk of complications.

Formal economic evaluation of treatment approaches for anemia of critical illness is generally lacking. Future studies may need to assess the cost per unit of RBC saved, which differs among institutions. Other pharmacoeconomic factors for consideration include morbidity and mortality of transfusion reactions, related infections, potential for medical errors, and availability of RBCs as a resource. Length of ICU stay, total hospital stay, length of time on mechanical ventilation, and mortality are other key factors.

ABBREVIATIONS

ACD: anemia of chronic disease
AIDS: acquired immunodeficiency syndrome
AIP: acute intermittent porphyria
CBC: complete blood count
CDC: Centers for Disease Control and Prevention
EPO: erythropoietin
ESA: erythropoiesis-stimulating agent
FDA: Food and Drug Administration
Fe^{2+}: ferrous iron
Fe^{3+}: ferric iron
G6PD: glucose-6-phosphate dehydrogenase
Hb: hemoglobin
Hct: hematocrit
HIV: human immunodeficiency virus
ICU: intensive care unit
IDA: iron-deficiency anemia
MCH: mean corpuscular hemoglobin
MCHC: mean corpuscular hemoglobin concentration
MCV: mean corpuscular volume
MMA: methylmalonic acid
NHANES: National Health and Nutrition Examination Survey
RBC: red blood cell
RDW: red blood cell distribution width
TIBC: total iron-binding capacity
USPSTF: U.S. Preventive Services Task Force
WHO: World Health Organization

CHAPTER 110

Coagulation Disorders

BETSY BICKERT POON, CHAR WITMER, AND JANE PRUEMER

KEY CONCEPTS

1. Hemophilia is an inherited bleeding disorder resulting from a congenital deficiency in factor VIII or IX.
2. The goal of therapy for hemophilia is to prevent bleeding episodes and their long-term complications and to arrest bleeding when it occurs.
3. Recombinant factor concentrates are usually first-line treatment of hemophilia because they have the lowest risk of infection.
4. The goal of therapy for von Willebrand disease is to increase von Willebrand factor and factor VIII levels to prevent bleeding during surgery or arrest bleeding when it occurs.
5. Factor VIII concentrates that contain von Willebrand factor are the agents of choice for treatment of type 3 von Willebrand disease and some type 2 von Willebrand disease, and for serious bleeding in type 1 von Willebrand disease.
6. Desmopressin acetate is often effective for treatment of type 1 von Willebrand disease. It may also be effective for treatment of some forms of type 2 von Willebrand disease.
7. The optimal approach for patients with disseminated intravascular coagulation remains to be determined. The goal of treatment is to diagnose and treat the underlying cause.
8. Prophylactic use of phytonadione can effectively prevent vitamin K–dependent bleeding in newborns.

A series of complex procoagulant and anticoagulant actions and reactions regulate hemostasis. Maintenance of hemostasis involves the interplay of four major components: (a) the vessel wall, (b) platelets, (c) the coagulation system, and (d) the fibrinolytic system. Coagulation disorders result from an imbalance in the regulation of these components. Bleeding disorders are the result of a decreased number of platelets, decreased function of platelets, coagulation factor deficiency, or enhanced fibrinolytic activity.

The traditional view of the coagulation cascade consists of intrinsic (propagation), extrinsic, and common pathways where coagulation proteins directed and controlled coagulation. This consisted of a sequential activation of clotting factors as shown in Figure 110–1. Although the historical model in Figure 110–1 shows the basic dependency of the various coagulation factors, it does not reflect the interactions with platelets and the endothelium. Thus it has been replaced by the cell-based model that more accurately describes these interactions (Fig. 110–2). This is known as the *tissue factor pathway* because it recognizes the central role of tissue factor in coagulation.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

REGULATION OF HEMOSTASIS

COAGULATION FACTORS

Twelve plasma proteins are considered coagulation factors (Table 110–1). The coagulation factors can be divided into three groups on the basis of biochemical properties: vitamin K–dependent factors (II, VII, IX, and X), contact activation factors (XI and XII, prekallikrein, high-molecular-weight kininogen), and thrombin-sensitive factors (V, VIII, XIII, and fibrinogen).

Coagulation factors circulate as inactive precursors (zymogens). Coagulation of blood entails a cascading series of proteolytic reactions. At each step, a clotting factor undergoes limited proteolysis and becomes an active protease (designated by a lowercase "a," as in Xa). These coagulation factors play key roles in the coagulation pathway.

VESSEL WALL AND PLATELETS

Two distinct pathways are involved in platelet activation: the collagen pathway and the tissue factor pathway. Activated platelets play a central role in primary hemostasis. Damage to a vessel wall initiates vasoconstriction and the exposure of collagen and tissue factor to blood. Exposed collagen triggers platelet recruitment and activation.[1] Tissue factor initiates coagulation via the tissue factor pathway, which leads to the generation of thrombin and activates platelets.

Primary hemostasis occurs in response to vascular injury and includes local vascular smooth muscle contraction, platelet activation, platelet adhesion and aggregation, and elaboration of procoagulant activity.[2] Platelet glycoprotein VI interacts with collagen from exposed vessels, and platelet glycoprotein Ib-V-IX interacts with collagen-bound von Willebrand factor to cause adhesion of platelets at the site.[1] Glycoprotein VI stimulates platelets to release granular contents, such as adenosine diphosphate and thromboxane A_2, which lead to platelet aggregation.[1] A platelet plug is formed that occludes the blood vessel lesion. Activated coagulation factors are generated at the site of bleeding on the activated platelets to form fibrin and stabilize the platelet plug. Factor XIIIa cross-links the fibrin and stabilizes the fibrin clot.[1]

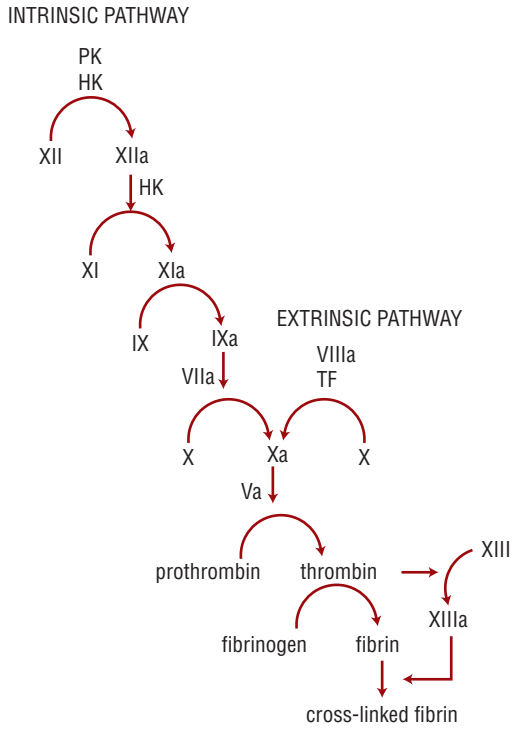

FIGURE 110-1. Cascade model of coagulation demonstrates activation via the intrinsic or extrinsic pathway. This model shows successive activation of coagulation factors proceeding from the top to the bottom where thrombin and fibrin are generated. (PK, prekallikrein; HK, high-molecular, weight kininogen; TF, tissue factor.) *(Reproduced from Roberts HR, Monroe DM, Hoffman M. Molecular biology and biochemistry of the coagulation factors and pathways of hemostasis. In: Lichtman MA, Beutler E, Coller BS, et al., eds. Williams Hematology. 7th edition. New York: McGraw-Hill; 2006:1665–1694.*

Simultaneously, the body works to localize clotting to the site of injury and prevent clotting in the intact vascular system. Unbound factors IIa, IXa, Xa, XIa, and XIIa are inactivated by antithrombin when they migrate to the endothelial cell surface. Heparin and heparin-like substances present on the surface of endothelial cells

TABLE 110-1 Blood Coagulation Factors

Factor[a]	Synonym	Biologic Half-life (h)	Blood Product Source
I	Fibrinogen	100–150	Cryoprecipitate (200–300 mg/bag)
II	Prothrombin	50–80	FFP, PCC
V	Proaccelerin	12–36	FFP
VII	Proconvertin	4–6	Recombinant VIIa, FFP, PCC
VIII	Antihemophilic factor	12–15	FFP, factor concentrates, cryoprecipitate
IX	Christmas factor	18–30	FFP, PCC, factor concentrates
X	Stuart-Power factor	25–60	FFP, PCC
XI	Plasma thromboplastin antecedent	40–80	FFP
XII	Hageman factor	50–70	Not associated with bleeding diathesis
XIII	Fibrin-stabilizing factor	150	FFP, cryoprecipitate, factor concentrate
VWF	von Willebrand factor	8–12	FFP, cryoprecipitate, factor concentrate

[a]Coagulation factors are numbered with Roman numerals in order of their discovery. The most common synonyms are listed. Factor III (tissue factor) and factor IV (calcium ions) have been omitted. There is no factor VI.
FFP, fresh-frozen plasma; PCC, prothrombin complex concentrate.

enhance the inhibitory capacity of antithrombin.[1] Thrombomodulin binds thrombin and activates protein C. Activated protein C and its cofactor, protein S, are vitamin K–dependent proteins that inactivate factor Va and VIIIa on the endothelial cell surface.

TISSUE FACTOR PATHWAY

Tissue factor is a membrane protein found in organs, circulating blood, and smooth muscle cells of vessel walls. Tissue factor is activated as a consequence of vessel wall damage or inflammatory cytokine release from endothelial cells or monocytes.[1,3] Coagulation is initiated when factor VIIa binds to activated tissue factor (Fig. 110–2).[1] The factor VIIa–tissue factor complex activates factors IX and X.[1,3] Activated platelets form complexes with factor IXa–factor VIIIa (tenase) and factor Xa-factor Va (prothrombinase).[1] Tenase activates factor X, and prothrombinase converts prothrombin to thrombin.[1] Thrombin activates platelets and catalyzes the conversion of fibrinogen to fibrin. Thrombin also amplifies coagulation by activating factors V, VIII, and XI, which leads to amplification of thrombin production by activated tenase and prothrombinase without the need to replenish active tissue factor.[1]

FIBRINOLYSIS

The coagulation system regulates fibrin clot formation, whereas the fibrinolytic system dissolves the polymerized clot and restores blood flow. As a regulatory mechanism for maintaining blood flow, the fibrinolytic system removes fibrin deposits and prevents formation of unnecessary fibrin clots. It also contributes to localized repair of damaged endothelium.

Plasminogen is the primary compound of the fibrinolytic enzyme system. Plasminogen activators include tissue-type plasminogen activator and urokinase-type plasminogen activator.[4] Activators convert plasminogen to plasmin in the presence of fibrin. Plasmin enzymatically digests fibrin, dissolves the clot, and releases a number of fibrin degradation products (FDPs). The interaction among plasminogen activators, plasminogen, and fibrin restricts the fibrinolytic activity to the site of the clot. Plasminogen activator inhibitor type 1 (PAI-1) blocks the plasminogen activators, whereas antiplasmin directly inhibits circulating plasmin to prevent systemic fibrinolysis.[4]

SIMPLE LABORATORY TESTS

The diagnosis of coagulation disorders can be established from a detailed clinical history, physical examination, and laboratory test results. The most common screening tests are prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time, platelet count, and bleeding time. The results of these standard laboratory procedures can distinguish bleeding disorders caused by defects in the intrinsic, extrinsic, and common coagulation pathways (see Fig. 110–1) or alterations in the number of functioning platelets. Specific assays of individual coagulation factors and platelet function tests can be performed after abnormalities are identified by initial screening tests. The following is a brief review of widely available tests (summarized in Table 110–2).

Bleeding Time and Platelet Function Analyzer

Bleeding time assesses platelet and capillary function. Bleeding time reflects the time to cessation of bleeding following a standardized skin cut. This technique is patient and operator dependent and has fallen out of favor.[2] The bleeding time is insensitive to mild platelet defects and does not consistently predict a bleeding tendency.[5] The platelet function analyzer (PFA-100) is an in vitro screen for platelet function.[5] This test measures the time to occlude an aperture in a cartridge containing a membrane coated with either collagen/epinephrine or collagen/adenosine phosphate.[2] Platelet function analyzers are becoming a common screening test for primary hemostasis. The test is more sensitive than bleeding time for evaluating von Willebrand disease but still has limitations.[2] The PFA-100 has not been validated in patients with liver dysfunction.[4]

A prolonged bleeding time can be caused by incorrect performance of the test, thrombocytopenia, platelet dysfunction, von Willebrand disease, use of antiplatelet drugs (i.e., aspirin), renal failure (uremia), fibrinogen disorders, abnormal blood vessels, or collagen disorders.

Prothrombin Time

PT assesses the activity of fibrinogen and factors II, V, VII, and X.[6] PT reflects the time required for fibrin strands to appear after the addition of tissue thromboplastin (tissue factor) and calcium chloride to the platelet-poor plasma. Thus PT provides information about the current synthetic capacity of the liver, the adequacy of vitamin K absorption, and the inhibition of clotting factor synthesis by warfarin. PT is expressed as an international normalized ratio that normalizes values based on the international sensitivity index of the test reagents for patients on vitamin K antagonists.[6]

Activated Partial Thromboplastin Time

aPTT measures the activity of the intrinsic system and common pathway (factors II, V, VIII, IX, X, XI, and XII, high-molecular-weight kininogen, prekallikrein, and fibrinogen). aPTT reflects the time required for a fibrin clot to form after a partial thromboplastin (tissue factor) and a foreign material (usually silica) are added to platelet-poor plasma. aPTT is widely used for monitoring heparin therapy.

Thrombin Time

The thrombin time measures the conversion of fibrinogen to fibrin and is affected by quantitative or qualitative abnormalities of fibrinogen, the presence of thrombin inhibitors, and fibrinogen degradation products. The thrombin time measures the time required for the formation and appearance of the fibrin clot after thrombin is added to plasma.

TABLE 110-2 Laboratory Procedures

Procedure	Identifies	Cause of Prolonged Value	Clinical Manifestations
Bleeding time	Platelet number and function	Acquired platelet disorders (uremia) Vasculitis Connective tissue disorder Thrombocytopenia Inherited qualitative platelet defects Antiplatelet drugs von Willebrand disease Factor V or XI deficiency Afibrinogenemia, dysfibrinogenemia	Bleeding from the gums Easy bruising Bleeding following surgery or tooth extraction Epistaxis Menorrhagia
Prothrombin time (PT)	Factors I, II, V, VII, X	Newborn Vitamin K deficiency Inherited factor deficiencies[a] Warfarin Liver disease Lupus anticoagulant Afibrinogenemia	Bleeding following surgery, trauma, etc. Easy bruising
Activated partial thromboplastin time (aPTT)	Factors I, II, V, VIII, IX, X	Inherited factor deficiencies[a] Lupus anticoagulant Heparin therapy Liver disease Afibrinogenemia	Joint and muscle bleeding Bleeding after surgery, trauma, etc.
	HMWK, prekallikrein		No bleeding manifestations
	Factor XII		Increased incidence of thrombotic disease possible with factor XII deficiency
	Factor XI		Variable bleeding tendency Bleeding following surgery, trauma, etc.
Thrombin time (TT)	Fibrinogen Inhibitors of fibrin aggregation	Afibrinogenemia, dysfibrinogenemia Heparin therapy	Lifelong hemorrhagic disease

[a]Bleeding manifestations dependent on factor levels.
HMWK, high-molecular-weight kininogen.

CONGENITAL COAGULATION DISORDERS

HEMOPHILIA

1 Hemophilia is a bleeding disorder that results from a congenital deficiency in a plasma coagulation protein. Hemophilia A (classic hemophilia) is caused by a deficiency of factor VIII, while hemophilia B (Christmas disease) is caused by a deficiency of factor IX. The incidence of hemophilia is approximately 1 in 5,000 male births, 80% to 85% hemophilia A and 15% to 20% hemophilia B.[7,8] There are no significant racial differences in the incidence of hemophilia.

Approximately one third of patients with hemophilia have a negative family history, presumably representing a spontaneous mutation. Both hemophilia A and hemophilia B are recessive X-linked diseases; that is, the defective gene is located on the X chromosome. The disease usually affects only males; females are carriers. Affected males have the abnormal allele on their X chromosome and no matching allele on their Y chromosome, their sons would be normal (assuming the mother is not a carrier), and their daughters would be obligatory carriers. Female carriers have one normal allele and therefore do not usually have a bleeding tendency. Sons of a female carrier and a normal male have a 50% chance of having hemophilia, whereas daughters have a 50% chance of being carriers. Thus there is a "skipped generation" mode of inheritance in which the female carriers, who are the children of patients with hemophilia, do not express the disease but can pass it on to the next male generation.

Hemophilia has been observed in a small number of females. It can occur if both factor VIII and IX genes are defective,[9,10] if a female patient has only one X chromosome, as in Turner syndrome, or if the normal X chromosome is excessively inactivated through a process called *lyonization* or highly skewed X inactivation.[11–13]

In 1984, researchers isolated and cloned the human factor VIII gene.[14] It is a large gene, consisting of 186 kilobases (kb).[14,15] More than 900 unique mutations in the factor VIII gene, including point mutations, deletions, and insertions, have been reported (*http://hadb.org.uk/*). Deletions and nonsense mutations are often associated with the more severe forms of factor VIII deficiency because no functional factor VIII is produced. In 1993, researchers identified an inversion in the factor VIII gene at intron 22 that accounts for approximately 45% of severe hemophilia A gene abnormalities.[16] That discovery has greatly simplified carrier detection and prenatal diagnosis in families with this gene mutation. A more recently discovered inversion mutation involving intron 1 of the factor VIII gene accounts for an additional 5% of severe hemophilia mutations.[17]

The factor IX gene, cloned and sequenced in 1982, consists of only 34 kb and thus is significantly smaller than the factor VIII gene.[15,18] Unlike the factor VIII gene in patients with severe hemophilia A, the factor IX gene in patients with hemophilia B has no predominant mutation. Direct gene mutation analysis is simpler in hemophilia B because of the smaller gene size, and to date more than 900 different mutations have been reported (*http://kcl.ac.uk/ip/petergreen/haemBdatabase.html*). Most of these mutations are single base pair substitutions. Approximately 3% of factor IX gene mutations are deletions or complex rearrangements, and the presence of these mutations is associated with a severe phenotype.[14]

Hemophilia B Leyden is a rare variant in which factor IX levels are initially low but rise at puberty. The mechanism underlying the pathogenesis of this disorder has been controversial. Some propose that the binding of androgen receptor and other transcription factors is responsible.[19,20] Recently, other molecular mechanisms for age-related gene regulation have been discovered and implicated in factor IX Leyden.[21] Identification of this genotype is clinically important because it confers a better prognosis.

TABLE 110-3 Laboratory and Clinical Manifestations of Hemophilia

	Severe (<0.01 units/mL)	Moderate (0.01–0.05 units/mL)	Mild (>0.05 units/mL)
Age at diagnosis	1 year	1–2 years	2 years–adult
Neonatal symptoms			
PCB	Usually	Usually	Rarely
ICH	Occasionally	Uncommonly	Rarely
Muscle/joint hemorrhage	Spontaneous	Minor trauma	Minor trauma
CNS hemorrhage	High risk	Moderate risk	Rare
Postsurgical hemorrhage (without prophylaxis)	Frank bleeding, severe	Wound bleeding, common	Wound bleeding
Oral hemorrhage following trauma, tooth extraction	Usually	Common	Common

Normal range of factor VIII/IX activity level is 0.5–1.5 units/mL (50%–150%). 1 unit/mL corresponds to 100% of the factor found in 1 mL of normal plasma.
CNS, central nervous system; ICH, intracranial hemorrhage; PCB, postcircumcisional bleeding.

Clinical Presentation

The characteristic bleeding manifestations of hemophilia include palpable ecchymoses, bleeding into joint spaces (hemarthroses), muscle hemorrhages, and excessive bleeding after surgery or trauma. The severity of clinical bleeding generally correlates with the degree of deficiency of factor VIII or factor IX. Factor VIII and factor IX activity levels are usually measured in units per milliliter, with 1 unit/mL representing 100% of the factor found in 1 mL of normal plasma.[22] Normal plasma levels range from 0.5 to 1.5 units/mL (50 to 150%). Patients with less than 0.01 units/mL (1%) of either factor are classified as having severe hemophilia, those with 0.01 to 0.05 units/mL (1%–5%) are moderate, and those with greater than 0.05 units/mL (5%) have mild hemophilia (Table 110–3).

Patients with severe disease experience frequent spontaneous hemorrhages and joint space bleeding, whereas those with moderate disease have excessive bleeding following mild trauma and rarely experience spontaneous hemarthroses. Patients with mild hemophilia may have so few symptoms that their condition can be undiagnosed for many years, and they usually have excessive bleeding only after significant trauma or surgery. Occasionally those with severe disease (less than 1% factor activity) may not display a severe phenotype; conversely, some with milder forms of the disease may have more severe bleeding. Patients with hemophilia usually present with clinical manifestations after age 1 year, when they begin to walk and increase their risk of bleeding.

Diagnosis

The diagnosis of hemophilia should be considered in any male with unusual bleeding. A family history of bleeding is helpful in the diagnosis but is absent in up to one third of patients.[23] Brothers of patients with hemophilia should be screened; sisters should undergo carrier testing.

Advances in molecular genetic analysis have greatly improved the accuracy of carrier status evaluation. Thus female relatives of patients with hemophilia who are at risk of being carriers should be tested. Additionally, the appropriate factor level should be measured in female carriers to identify those with levels less than 0.3 units/mL (30%) who themselves might be at risk for bleeding.

CLINICAL PRESENTATION OF HEMOPHILIA

Signs and Symptoms

- Ecchymoses (palpable)
- Hemarthrosis (especially knee, ankle, and elbow)
- Joint pain
- Joint swelling and erythema
- Decreased range of motion
- Muscle hemorrhage
- Swelling
- Pain with motion of affected muscle
- Signs of nerve compression
- Potential life-threatening blood loss, especially with thigh bleeding
- Oral bleeding with dental extractions or trauma
- Hematuria
- Intracranial hemorrhage (spontaneous or following trauma)
- Excessive bleeding with surgery

Laboratory Testing

- Prolonged aPTT
- Decreased factor VIII or factor IX level
- Normal PT
- Normal platelet count
- Normal von Willebrand factor antigen and activity
- Normal bleeding time

Patients with severe hemophilia A should be tested for the common factor VIII gene inversions. If the patient has this mutation, female family members should undergo testing to determine whether they also have the mutation and thus are carriers. In patients with hemophilia A who lack the inversion mutation, the gene can be sequenced to determine the exact mutation.[24,25] Techniques for determining carrier status in families with hemophilia B are similar, although no predominant mutation like the factor VIII inversion has been found. The smaller size of the factor IX gene facilitates direct DNA mutational analysis.[25]

Hemophilia can be diagnosed prenatally by chorionic villus sampling in gestational weeks 10 to 11 or by amniocentesis after 15 weeks' gestation.[15,24] Fetal blood can be sampled and assayed directly for factor VIII levels by 18 to 20 weeks' gestation.[15,24] This procedure is less useful for diagnosing factor IX deficiency because factor IX levels are physiologically low in fetuses and infants.

TREATMENT

Hemophilia

The comprehensive care of hemophilia requires a multidisciplinary approach. The patient is best managed in specialized centers with trained personnel and appropriate laboratory, radiologic, and pharmaceutical services. The healthcare team includes hematologists, orthopedic surgeons, nurses, physical therapists, dentists, genetic counselors, psychologists, pharmacists, case managers, and social workers.

Patients with hemophilia should receive routine immunizations, including immunization against hepatitis B. Hepatitis A vaccine is also recommended for patients with hemophilia because of the risk (albeit small) of transmitting the causative agent through factor concentrates.[26] Use of a small-gauge needle can prevent excessive bleeding. Many healthcare providers advocate subcutaneous rather than intramuscular immunizations to decrease the risk of intramuscular bleeding or hematoma formation.

A few special considerations apply to the perinatal care of male infants of hemophilia carriers. Intracranial or extracranial hemorrhage has been estimated to occur in 1% to 4% of newborns with hemophilia.[27] Vacuum extraction and forceps delivery increase the risk of cranial bleeding. Elective cesarean section has not been shown to prevent intracranial bleeding. There is no clear consensus on the optimal mode of delivery or the use of prophylactic factor replacement in male infants of hemophilia carriers.[27] Circumcision should be postponed until a diagnosis of hemophilia is excluded. Factor levels can be assayed from cord blood samples or from peripheral venipuncture. Arterial puncture should be avoided because of the risk of hematoma formation. If an infant has hemophilia, many clinicians recommend a screening head ultrasound to rule out an intracranial hemorrhage prior to discharge from the nursery.

2 Intravenous factor replacement therapy for the treatment or prevention of bleeding is the mainstay of treatment of hemophilia. Parents usually learn how to infuse with factor concentrate to facilitate home treatment. Older children and adult patients learn self-administration. Home healthcare nursing support may be helpful, particularly for the youngest patients in whom venous access may be difficult. In the setting of poor venous access a central line may be indicated. Administration of factor at home is more convenient for families and allows for earlier treatment of acute bleeding episodes. However, serious bleeding episodes always require medical evaluation.

HISTORY OF HEMOPHILIA TREATMENT

Therapy for hemophilia has undergone dramatic advances over the past few decades. Fifty years ago, administration of fresh-frozen plasma was the only available treatment. The introduction of cryoprecipitate in the early 1960s allowed more specific therapy for hemophilia A.[14] Intermediate-purity factor VIII and IX concentrates became available in the 1970s.[14] Plasma-derived factor concentrates are made from the donations of thousands of people. Contamination of plasma pools with hepatitis B, hepatitis C, and the human immunodeficiency virus (HIV) during the late 1970s and early 1980s resulted in transmission to most patients with severe hemophilia. Since the mid-1980s, plasma-derived concentrates have been manufactured with a variety of virus-inactivating techniques, including dry heat, pasteurization, and treatment with chemicals (e.g., solvent detergent mixtures).[14] Since 1986, no transmission of HIV through factor concentrates to patients with hemophilia in the United States has been reported.[14] Protein purification, introduced in the 1990s, produced high-purity concentrates with increased amounts of factor VIII or factor IX relative to the product's total protein content. Recombinant factor VIII and then factor IX also became available.[14] The first-generation recombinant factor VIII products utilize human and animal proteins in culture and add human albumin as a protein stabilizer.[14] Second-generation recombinant factor VIII concentrates removed albumin as a protein stabilizer, and third-generation products lack human and animal proteins in the culture media.[28] Gene therapy for treatment of hemophilia is now in the early stages of clinical trials.

HEMOPHILIA A

Table 110–4 summarizes the factor VIII products currently available in the United States. Most patients are treated with high-purity products. In general, products that have the lowest risk of transmitting

TABLE 110-4 Factor Concentrates

Brand Name	Product Type	Viral Inactivation or Exclusion Method	Other Contents
Factor VIII concentrates			
Alphanate	Plasma	Solvent detergent, dry heat	Albumin, heparin, vWF
Hemophil M	Plasma	Solvent detergent, monoclonal antibody	Albumin
Humate-P	Plasma	Pasteurization	Albumin, vWF
Koate-DVI	Plasma	Solvent detergent, dry heat	Albumin, heparin, vWF
Monarc-M	Plasma	Solvent detergent, monoclonal antibody	Albumin
Monoclate P	Plasma	Pasteurization, monoclonal antibody	Albumin
Advate	Recombinant	None	
Bioclate	Recombinant	None	Albumin
Helixate FS	Recombinant	Solvent detergent	Albumin (fermentation only); sucrose
Kogenate FS	Recombinant	Solvent detergent, monoclonal antibody	Albumin (fermentation only); sucrose
Recombinate	Recombinant	Monoclonal antibody	Albumin
ReFacto B domain deleted	Recombinant	None	Albumin (fermentation only); sucrose
Factor IX Concentrates			
AlphaNine SD	Plasma	Solvent detergent, filtered	Heparin
Mononine	Plasma	Monoclonal antibody, ultrafiltration	Heparin
BeneFix	Recombinant	None	
aPCC			
Autoplex T	Plasma	Dry heat	Heparin, IIa, VIIa, trace VIIIa, IXa, Xa
Feiba VH Immuno	Plasma	Vapor heat	IIa, VIIa, VIIIa, IXa, Xa
PCC			
Bebulin VH	Plasma	Vapor heat	Heparin, II, IX, X
Profilnine SD	Plasma	Solvent detergent	II, VII, IX, X
Proplex T	Plasma	Dry heat	Heparin, II, VII, IX, X
Other			
NovoSeven	Recombinant VII	None	
Hyate:C[a]	Porcine VIII	Freeze-dried	Citrate

aPCC, activated prothrombin complex concentrate; PCC, prothrombin complex concentrate; vWF, von Willebrand factor.
[a]No longer available in the United States.

infectious disease should be used. Thus recombinant products, when available, are generally used rather than plasma-derived products.

Recombinant Factor VIII

3 Derived from cultured Chinese hamster ovary cells or baby hamster kidney cells transfected with the human factor VIII gene, recombinant factor VIII is produced with recombinant DNA technology.[14] Because it is not derived from blood donations, the risk of transmitting infections through administration of recombinant factor VIII is low. For this reason, recombinant products are generally favored over plasma-derived products. There is still a small risk of viral infection of the cell lines used to produce the clotting factor.[29] Furthermore, human and/or animal proteins are utilized in the production process of some recombinant products.[28] Therefore, these products have a theoretical risk of transmitting infection, although hepatitis and HIV infection have never been reported with their use.[14] The presence of parvovirus B19 DNA has been reported in recombinant factor VIII products.[30] First-generation recombinant factor VIII products contain human albumin as a stabilizing protein.[14] Second-generation recombinant factor VIII products add sucrose instead of human albumin as a stabilizer, but human albumin is utilized in the culture process. One second-generation product (ReFacto) has deletion of the B domain of the factor VIII gene, yielding a smaller protein product.[14] This B domain does not appear to be necessary for coagulation function. Third-generation recombinant factor VIII products contain no human protein in either the culture or the stabilization processes.[28]

Clinical trials have demonstrated that recombinant factor VIII products are comparable in effectiveness to plasma-derived products.[14] The risk of patients with severe hemophilia A developing an inhibitory antibody to factor VIII with use of recombinant factor VIII is 25% to 32%.[31] There is concern that this risk is higher than what was previously reported with plasma-derived products. The difference may be partly attributable to more frequent screening for inhibitors in the recombinant product trials, with detection of transient inhibitors that might have been missed in the trials with plasma-derived products.[32] A recent multicenter retrospective cohort study of 316 patients with severe hemophilia did not find a difference in inhibitor development in patients who received recombinant products versus plasma-derived products.[33] A prospective international clinical trial comparing inhibitor development in patients receiving recombinant products versus plasma-derived products has been initiated.

Plasma-Derived Factor VIII Products

Several different plasma-derived factor VIII products are available (see Table 110–4). These products are derived from the plasma of thousands of donors and therefore can potentially transmit infection. Donor screening, testing plasma pools for evidence of infection, viral reduction through purification steps, and viral inactivation procedures (e.g., dry heat, pasteurization, and solvent detergent treatment) have all resulted in a safer product.[28] No cases of HIV transmission from factor concentrates have been reported since 1986.[14] However, isolated cases of hepatitis C infection with use of plasma-derived products have been reported.[14] Additionally, outbreaks of hepatitis A viral infections associated with plasma-derived products, likely because solvent detergent treatment does not inactivate this nonenveloped virus, have been reported. Parvovirus has been reported to be present in both plasma-derived and recombinant factor VIII products.[29,30] Finally, possible infection with as yet unidentified viruses that currently used methods would not inactivate remains a concern. There is a new concern that prion disease may be present in plasma derived factor VIII products.[29,34]

Factor VIII concentrates can be classified according to their level of purity, which refers to the specific activity of factor VIII in the product. Cryoprecipitate is a low-purity product. Cryoprecipitate also contains von Willebrand factor, fibrinogen, and factor XIII. Current American Association of Blood Banks standards call for a minimum of 80 international units of factor VIII per pack.[14] This product is no longer considered a primary treatment of factor VIII deficiency in countries where factor VIII concentrates are available because cryoprecipitate does not undergo a viral inactivation process. Intermediate-purity products have a specific activity of factor VIII of 5 units/mg of protein, whereas high-purity products have up to 2,000 units/mg of protein.[14] Ultrahigh-purity plasma-derived products are prepared with monoclonal antibody purification steps and have a specific activity of 3,000 units/mg of protein prior to addition of albumin as a stabilizer.

Factor VIII Concentrate Replacement

Appropriate dosing of factor VIII concentrate depends on the half-life of the infused factor, the patient's body weight, and the volume of distribution. The presence or absence of an inhibitory antibody to factor VIII and the titer of this antibody also influence treatment. Recovery studies, which measure the immediate postinfusion factor level, and survival studies, which assess the half-life of the factor, can establish patient-specific pharmacokinetics. The location and magnitude of the bleeding episode determine the percent correction to target as well as the duration of treatment. Serious or life-threatening bleeding requires peak factor levels of greater than 0.75 to 1 units/mL (75%–100%); less severe bleeding may be treated with a goal of 0.3 to 0.5 units/mL (30%–50% peak plasma levels. Table 110–5 provides general guidelines for the management of bleeding in different locations.

Factor VIII is a large molecule that remains in the intravascular space. Therefore, the plasma volume (approximately 50 mL/kg) can be used to estimate the volume of distribution. In general, each unit of factor VIII concentrate infused per kilogram of actual body weight yields a 2% rise in plasma factor VIII levels. The following equation can be used to calculate an initial dose of factor VIII:

$$\text{Factor VIII (units)} = (\text{Desired level [in units/mL]} - \text{Baseline level [in units/mL]}) \times 0.5 \times (\text{Weight [in kilograms]}).$$

The baseline level is usually omitted from the equation because it is negligible compared with the desired level. The half-life of factor VIII ranges from 8 to 15 hours. It is generally necessary to administer half of the initial dose approximately every 12 hours to sustain the desired level of factor VIII. A single treatment may be adequate for minor bleeding, such as oral bleeding or slight muscle hemorrhages. However, because of the potential for long-term joint damage with hemarthroses, 2 or 3 days of treatment is often recommended for these bleeds. Serious bleeding episodes may require maintenance of 70% to 100% factor activity for 1 week or longer. As previously mentioned, factor VIII dosing depends on several variables, and each case must be considered individually. Individual pharmacokinetics may help guide treatment, particularly for serious bleeding episodes.

Alternatively, factor VIII can be administered as a continuous infusion when prolonged treatment is required (e.g., in the perioperative period or for serious bleeding episodes). Infusion rates ranging from 2 to 4 units/kg per hour are usually given in fixed-dose continuous infusion protocols, with the aim of maintaining a steady-state level of 60% to 100%.[35,36] Administration of factor concentrate via continuous infusion may reduce factor requirements by 20% to 50% because unnecessarily high peaks of factor VIII that occur with bolus injections are avoided.[36] A gradual decrease in factor VIII clearance during the first 5 to 6 days of treatment contributes to the lower factor concentrate requirements.[36] Daily monitoring of factor level can help determine the appropriate rate of infusion.

Administration of factor VIII concentrate via continuous infusion has been shown to be safe and effective, and it may be more convenient than bolus therapy for hospitalized patients.[35,36] The advantages of continuous infusion include maintenance of a steady-state plasma level with avoidance of potentially subtherapeutic trough levels and a reduction in cost associated with decreased factor requirements. A potential side effect with continuous infusion is thrombophlebitis at the delivery site. Concomitant infusion of saline or the addition of heparin (2–5 units/mL) to the infusion bag can minimize this risk.[36] Bacterial contamination of the concentrate is another theoretical concern, and preparation of the infusion bag should occur under sterile conditions (i.e., under laminar flow).[36] Finally, concerns about the stability of the formulations appear to be unwarranted, as most high-purity factor VIII concentrates have been shown to remain stable for at least 7 days after reconstitution.[36] Exposure of factor VIII to light for 10 hours postreconstitution can cause a 30% decrease in the activity.[36] It would be prudent to shield the container with foil wrap or an appropriate bag.

TABLE 110-5 Guidelines for Factor Replacement Therapy for Hemorrhage in Hemophilia A and B

Site of Hemorrhage	Desired Hemostatic Factor Level (% of normal)	Comments
Joint	50%–70%	Rest/immobilization/physical therapy rehabilitation following bleed; several doses may be necessary to prevent or treat target joint
Muscle	30%–50% for most sites	
	70%–100% for thigh, iliopsoas, or nerve compression	Risk of significant blood loss with femoral/retroperitoneal bleed; bed rest for iliopsoas or other retroperitoneal bleeding
Oral mucosa	30%–50%	May try antifibrinolytic or topical thrombin prior to factor replacement for minor bleeding; higher factor levels may be needed for tongue swelling or risk of airway compromise; antifibrinolytic therapy should be used following factor replacement; do not use with aPCCs or PCCs
Gastrointestinal	Initially 100%, then 30% until healing occurs	Endoscopy is highly recommended; antifibrinolytic therapy may be useful
Hematuria	30% if no trauma	
	70%–100% if traumatic	If no pain or trauma, consider bed rest and fluids for 24 hours; factor should be given if hematuria persists; evaluate if hematuria persists; if trauma to abdomen or back, perform imaging and give aggressive factor replacement
Central nervous system	Initially 100%, then 50%–100% for 10–14 days	Lumbar puncture requires prophylactic factor coverage
Trauma or surgery	Initially 100%, then 50% until wound healing complete	Perioperative and postoperative management plan must be in place preoperatively; evaluation for inhibitors is crucial prior to elective surgery

aPCC, activated prothrombin complex concentrate; PCC, prothrombin complex concentrate.

Other Pharmacologic Therapy

Treatment with desmopressin acetate is often adequate for minor bleeding episodes in patients with mild hemophilia A. A synthetic analogue of the antidiuretic hormone vasopressin, desmopressin causes release of von Willebrand factor and factor VIII from endogenous endothelial storage sites. It appears to be most effective in patients with higher baseline factor VIII levels (0.1–0.15 units/mL or 10–15%).[37] The recommended dose of desmopressin is 0.3 mcg/kg diluted in 50 mL of normal saline and infused IV over 15 to 30 minutes.[15,37] Patients with mild or moderate hemophilia A should undergo a desmopressin trial to determine their response to this medication. At least a twofold rise in factor VIII to a minimal level of 0.3 units/mL (30%) within 60 minutes is considered an adequate response.[38] In adults with mild hemophilia A, the response rate to desmopressin has been reported to be 80% to 90%.[38] Pediatric studies have reported a lower rate of response ranging from 40% to 47%.[38] Furthermore, the pediatric response rate was related to age; some nonresponding children became responders at an older age.[38]

Infusion of desmopressin can be repeated daily for up to 2 to 3 days. Tachyphylaxis, an attenuated response with repeated dosing, may develop after that time. The factor increase after the second dose of desmopressin is approximately 30% lower than after the initial dose.[37] Factor concentrate therapy may be necessary if the patient requires additional treatment. Factor levels should be measured to ensure that an adequate response has been achieved. Treatment with desmopressin will not result in hemostasis in patients who have severe hemophilia and those who are only marginally responsive. Desmopressin should not be used as primary therapy for life-threatening bleeding episodes such as intracranial hemorrhage or for major surgical procedures when a minimum factor VIII concentration of 0.7 to 1 units/mL (70%–100% [0.70–1.00]) is required.[37]

Desmopressin can be administered intranasally via a concentrated nasal spray.[37,38] It elicits a slower and less marked response, with a peak effect in 60 to 90 minutes after administration, somewhat longer than with desmopressin administered intravenously.[37,38] The dosage is one spray (150 mcg) for patients who weigh less than 50 kg (110 lbs) and two sprays (300 mcg) for those who weigh more than 50 kg (110 lbs).[15] The nasal spray may serve as an alternative to the intravenous formulation, especially in patients with mild bleeding episodes.

Few adverse effects are associated with desmopressin. The most commonly observed side effect is facial flushing.[37] Less frequently reported side effects include mild headaches, increased heart rate, and decreased blood pressure. Thrombosis is a rare complication associated with desmopressin.[38] Because of its antidiuretic effects, desmopressin has the potential to cause water retention, which may lead to severe hyponatremia. This may be a particular problem in children younger than 2 years, in whom hyponatremic seizures have been reported.[36] Therefore, desmopressin should be used with caution in this age group.[37,38] Patients with congestive heart failure may be at increased risk for developing hyponatremia with use of desmopressin.[37] Fluid restriction for 24 hours after the desmopressin dose and monitoring of urine output are recommended with desmopressin administration.[38]

Antifibrinolytic therapy inhibits clot lysis and is therefore a useful adjunctive therapy for the treatment of hemophilia. Antifibrinolytic agents are particularly beneficial for treatment of oral bleeding because of the high concentration of fibrinolytic enzymes present in saliva. Two antifibrinolytics are aminocaproic acid and tranexamic acid. Aminocaproic acid is given at a dosage of 100 mg/kg (maximum 6 g) every 6 hours and can be administered orally or intravenously.[15] The dosage of tranexamic acid is 25 mg/kg (maximum 1.5 g) orally every 8 hours or 10 mg/kg (maximum 1 g) intravenously every 8 hours.[15]

HEMOPHILIA B

Therapeutic options for hemophilia B have improved greatly over the past several years, first with the development of monoclonal antibody–purified plasma-derived products and then with the licensure of recombinant factor IX. Products currently available in the United States for treatment of hemophilia B are listed in Table 110–4.

Recombinant Factor IX

First marketed in the United States in 1999, recombinant factor IX is produced in Chinese hamster ovary cells transfected with the factor IX gene.[14] Blood and plasma products are not used to produce recombinant factor IX or to stabilize the final product; thus recombinant factor IX has an excellent viral safety profile.[14] Clinical trials have shown the product to be safe and efficacious in the treatment of acute bleeding episodes and in the management of bleeding associated with surgical procedures.[14,39] Although the half-life of recombinant factor IX is similar to that of the plasma-derived products, recovery is approximately 30% lower.[40] As a result, doses of recombinant factor IX concentrate must be higher than those of plasma-derived products to achieve equivalent plasma levels. Because individual pharmacokinetics may vary, recovery and survival studies should be performed to determine optimal treatment.[14,39,40] Recombinant factor IX is considered the treatment of choice for hemophilia B.

Plasma-Derived Factor IX Products

High-purity factor IX plasma concentrates have been available in the United States since the early 1990s.[14,39,40] These products are derived from plasma through biochemical purification and monoclonal immunoaffinity techniques. Other viral inactivation measures, such as solvent detergent or chemical treatment, are also used.

Before the high-purity products were approved for use, hemophilia B patients were treated with factor IX concentrates that also contained other vitamin K–dependent proteins (factors II, VII, and X), known as prothrombin complex concentrates (PCCs). These products contain small amounts of activated factors generated during processing, and their use has been associated with thrombotic complications, including deep-vein thrombosis, pulmonary embolism, myocardial infarction, and disseminated intravascular coagulation (DIC).[14,41] The risk of such complications is highest in patients who are receiving high or repeated doses of PCCs, in those who have hepatic disease (the liver removes the activated factors from circulation), in neonates, and in patients who have experienced crush injuries or who are undergoing major surgery.[14,41] Concomitant use of PCCs and antifibrinolytics should be avoided because of the risk for thrombosis.

Because of the lower purity of PCCs and their thrombogenic potential, these products are not first-line treatment of hemophilia B, although they are still used for treatment of patients with hemophilia A or B who have developed inhibitory antibodies against factor VIII or factor IX, respectively. High-purity factor IX concentrates have excellent efficacy in the treatment of bleeding episodes and in the control of bleeding associated with surgical procedures.[42] Their viral safety profile has been reported to be excellent, and the risk of thromboembolic complications is low.[42]

Factor IX Concentrate Replacement

Factor IX is a relatively small protein. Unlike factor VIII, it is not limited to the intravascular space; it also passes into the extravascular compartment.[40] This results in a volume of distribution that is about twice that of factor VIII. In general, for plasma-derived

factor IX concentrates, each unit of factor IX infused per kilogram of actual body weight yields a 1% rise in the plasma level of factor IX (range 0.67%–1.28%).[14] The following equation can be used to calculate the initial dose:

Plasma-derived factor IX (units) = (Desired level − Baseline level) × (Weight [in kilograms]).

As with the similar calculation for factor VIII dosing, the baseline level term can be omitted from the formula. Because recovery of recombinant factor IX is lower than that of the plasma-derived products, the following adjustment is made:

Pediatric dosing:

Recombinant factor IX (units) = (Desired level[in units/mL] − Baseline level [in units/mL]) × 1.4 × (Weight [in kilograms]).

Adult dosing:

Recombinant factor IX (units) = (Desired level [in units/mL] − Baseline level [in units/mL]) × 1.2 × (Weight [in kilograms]).

A recovery study to determine optimal dosing is recommended for patients who receive recombinant factor IX because of the wide interpatient variability in pharmacokinetics.

Because the half-life of factor IX is approximately 24 hours, dosing can be less frequent than with factor VIII. Table 110–5 provides general guidelines for dosing factor IX, based on the site and severity of the bleeding episode. As with factor VIII replacement therapy, individual pharmacokinetics may vary, and monitoring the patient's factor IX levels helps optimize therapy.

PROPHYLACTIC REPLACEMENT THERAPY

Traditionally, factor concentrates for hemophilia patients have been given on demand, as the bleeding episode occurs. However, recurrent joint bleeding can damage the joint and lead to development of severe physical disability. Thus it would be preferable to prevent bleeding episodes and avoid the resultant damage. Known as *prophylactic factor replacement therapy*, this approach entails regular infusion of concentrate to maintain the deficient factor at a minimum of 0.01 units/mL (1%).

In effect, prophylactic replacement therapy converts severe hemophilia into a milder form of the disease. The rationale for this approach is that patients with moderate hemophilia rarely experience spontaneous hemarthroses, and they have a much lower incidence of chronic arthropathy. Patients with hemophilia A usually require 25 to 40 units of factor VIII per kilogram of body weight, given every other day or three times per week.[15] For hemophilia B, the usual dosage is 40 to 100 units/kg of factor IX given twice weekly instead of three times weekly because of the longer half-life of factor IX.[43]

Primary prophylaxis is regular replacement therapy started at a young age (usually before age 2 years), prior to the onset of joint bleeding.[44,45] In the Swedish experience, children who began prophylaxis at age 1 to 2 years experienced almost no bleeding episodes and had normal joint examinations and radiographs over a 5-year period.[14,46] Secondary prophylaxis begins after significant joint bleeding has already occurred. It is associated with a significant reduction in the number of joint bleeding episodes and a better clinical and orthopedic outcome.[47,48] However, radiographic evidence of joint disease rarely improves and often progresses despite the institution of secondary prophylaxis.[14,46] Therefore, it may not be possible to avoid chronic arthropathy when prophylaxis is initiated after significant joint bleeding has already occurred; this supports a need for earlier intervention. Manco-Johnson et al. completed the first pediatric randomized clinical trial comparing prophylaxis to enhanced episodic treatment to prevent joint disease in boys (age <30 months) with severe hemophilia.[49] They demonstrated that prophylaxis prevented joint damage and decreased the frequency of joint and other hemorrhages in boys with hemophilia.[49]

In 2001 the Medical and Scientific Advisory Council of the National Hemophilia Foundation of the United States recommended primary prophylaxis (prior to onset of frequent bleeding) beginning at age 1 to 2 years for children with severe hemophilia. The use of primary prophylaxis has many challenges and has not been widely accepted in the United States. Many institutions continue to use some form of secondary prophylaxis, in which prophylaxis is started after a pattern of bleeding has been established.

Several disadvantages are associated with primary prophylaxis. Perhaps most important is the high cost of prophylactic replacement therapy. Factor requirements are estimated to be twofold to threefold higher with prophylactic regimens than with treatment on demand.[46,50] Use of individual pharmacokinetics to titrate dosage may help to lessen costs.[50] Other issues to consider are the inconvenience to families and possible difficulties with compliance. Central venous lines may be necessary for frequent administration of factor concentrates, particularly in children younger than 5 years, who are at the age targeted for initiation of primary prophylaxis regimens. Potential complications of central venous access include surgical risks, infection, and catheter-related deep-vein thrombosis.[51] Catheter-related infections are common in patients with hemophilia and have been reported to occur in up to 0.2-2 per 1,000 catheter days.[52] Catheter-related infectious complications appear to be more common in hemophilia patients who have developed inhibitory antibodies.[52] Finally, routine use of primary prophylaxis may overtreat some patients with severe hemophilia who do not have a severe clinical phenotype.

CLINICAL CONTROVERSY

Hemophilia patients may receive prophylactic factor concentrate therapy to prevent or decrease bleeding episodes, or they may receive on-demand factor concentrate therapy in response to a bleeding episode. In addition, prophylaxis may be primary or secondary. Controversy exists over whether the benefits of prophylaxis justify the cost, appropriate time to initiate prophylaxis, and appropriate dosing for prophylaxis.

TREATMENT OF INHIBITORS IN HEMOPHILIA

Neutralizing antibodies to factor VIII and IX, known as *inhibitors*, develop in a subset of patients with hemophilia, challenging the management of these patients. The development of an inhibitor is the most serious complication of factor replacement therapy. The reported prevalence of inhibitor development varies considerably, depending on the population studied, the study design, the method of detection, and the frequency and duration of testing. In one systematic review, the overall prevalence of inhibitors in unselected patients with hemophilia was 5% to 7%.[32] The prevalence among patients with severe hemophilia was approximately 12% to 13%, which is higher than for unselected patients.[32] The reported cumulative incidence of inhibitors in hemophilia B is much lower, occurring in only 1% to 4% of patients.[31]

Most inhibitors develop in childhood, often after relatively few exposure days (median 9–12 days).[31] Patients with severe hemophilia

are much more likely to develop inhibitors than those with milder forms of the disease.[32] It is possible that the low levels of factor produced in patients with mild and moderate hemophilia induce immune tolerance in these individuals. In contrast, factor levels are undetectable in patients with severe hemophilia, and infused factor VIII, regarded as a foreign protein, may provoke an antibody response. The rate of inhibitor formation varies even among patients with identical mutations, which suggests that host factors modify the risk. One possibility is that human leukocyte antigen (HLA) genotype may influence the risk of inhibitor formation, but studies have been inconclusive.[53]

Inhibitors are usually immunoglobulins of the immunoglobulin G subclass that are directed against the factor coagulant portion of the complex. The presence of an inhibitor is suspected when a decreased clinical response to factor replacement is observed. It may be discovered incidentally on routine laboratory screening. Inhibitors are measured with the Bethesda assay, and titers are reported in Bethesda units (BU). One BU is the amount of inhibitor needed to inactivate half of the factor VIII or factor IX in a mixture of inhibitor-containing plasma and pooled normal plasma.[14] Patients with inhibitors to factor VIII or factor IX are divided into two groups: low responders, who have low levels of inhibitors (<5 BU/mL) and generally have little or no rise in antibody titers after exposure to the factor; and high responders (>5 BU/mL), who have higher inhibitor levels and develop an increase in antibody titer after exposure (anamnestic response).[14]

Therapy for patients with inhibitors involves treatment of acute bleeding episodes and treatment directed at eradicating the inhibitor. The inhibitor titer, the site and magnitude of bleeding, and the patient's past response to therapy determine the approach to treatment. For patients with a low inhibitor titer, administration of high doses of the specific factor can often control bleeding episodes. Two to three times the usual replacement dose and more frequent dosing intervals are often necessary to overcome the antibody. Factor level monitoring and clinical assessments help to evaluate the adequacy of treatment. Additional supportive measures, such as immobilization and administration of antifibrinolytic agents, should be used, where appropriate.

In the presence of a high-titer inhibitor, it may be impossible to administer enough factor VIII or factor IX to neutralize the antibody and achieve a hemostatic plasma level. Therefore, in these patients treatment of bleeding episodes consists of use of agents that bypass the factor to which the antibody is directed. These include PCCs, activated PCCs, and recombinant activated factor VII.

PCCs contain the vitamin K–dependent factors II, VII, IX, and X. Small quantities of activated factors VII and IX are present in these products. Activated PCCs (aPCCs) contain greater quantities of the activated factors.[54] The usual dosage is 50 to 100 units/kg administered every 12 to 24 hours, depending on the severity of the bleeding episode.[32] The maximum dose should not exceed 200 units/kg/day. Use of PCCs and aPCCs, when not restricted to one or two doses, is effective in obtaining hemostasis in approximately 80% of bleeding episodes in patients with inhibitors, and aPCCs appear to be more effective than PCCs. As previously mentioned, there is a risk of serious thrombotic complications, including pulmonary emboli, deep-vein thrombosis, and myocardial infarction associated with use of PCCs and aPCCs.[54] Additionally, because these products contain trace amounts of factor VIII and larger amounts of factor IX, they can stimulate an anamnestic response in patients with hemophilia A and, more commonly, in those with hemophilia B.[54] Other minor side effects include dizziness, nausea, hives, flushing, and headaches.[54] Patients with factor IX inhibitors occasionally develop severe allergic reactions in response to infusion of factor IX–containing products, so these patients should be monitored closely.[55]

Recombinant factor VIIa, a newer bypassing agent, is thought to be hemostatically active only at the site of tissue injury where tissue factor is present; thus the risk of systemic thrombotic events associated with this agent is minimal.[56] Additionally, because recombinant VIIa is not a plasma-derived product, both viral transmission and anamnestic responses to factor VIII or factor IX are unlikely.[54] The initial dose for bleeding episodes ranges from 35 to 120 mcg/kg.[54] Doses of 70 mcg/kg or higher are more effective, and often a dose of 90 to 120 mcg/kg is used for treatment of patients with hemophilia and inhibitors.[54,57] A drawback is the product's short half-life, which necessitates dosing every 2 hours. Continuous infusion of recombinant factor VIIa, which may be more convenient and cost effective, has been successful, although studies are limited. Recombinant factor VIIa appears to be efficacious in controlling bleeding episodes and managing hemophilia during surgical procedures.[54] Patients treated with bypassing agents must be monitored clinically because no laboratory test directly measures the effectiveness of treatment.

Porcine factor VIII is an alternative therapeutic option for patients who have hemophilia A and inhibitors. The rationale is that porcine factor VIII is enough like human factor VIII to participate in the coagulation cascade, yet most factor VIII inhibitors have absent or only weak neutralizing activity against nonhuman factor VIII. However, cross-reactivity with porcine factor VIII does occur, and a high titer of antibody against porcine factor VIII can develop. Although the rise in antibody titer with porcine factor VIII is generally lower than that seen with administration of human factor VIII, anamnestic rises in inhibitor titers to both porcine and human factor VIII may occur and can limit future use.[54] Other potential side effects include severe allergic reactions and thrombocytopenia.[54] Porcine factor VIII is no longer commercially available but can be obtained for use in specific patients. Because of these limitations, porcine factor VIII is usually indicated only after the patient has not responded to recombinant factor VIIa and PCC or when the patient has severe hemorrhages.[54] An advantage to porcine factor VIII is that treatment response can be monitored with factor VIII levels.

The ideal therapy for patients with hemophilia and inhibitors eradicates the inhibitor so that future treatment with factor VIII or factor IX concentrates is possible. Immune tolerance therapy, which involves the regular infusion of high doses of the factor to which the antibody is directed, may accomplish this eradication. A variety of different dosing regimens, ranging from 25 units/kg every other day to more than 200 units/kg every day, have been used. Some treatment protocols include adjunctive immunomodulatory therapy, such as administration of cyclophosphamide, prednisone, and intravenous immune globulin.[58] The overall success rate is 50% to 70% and is higher in patients with low inhibitor titers and in those with recent development of inhibitor.[53] Weeks to years of therapy may be required to eradicate the antibody. Unfortunately, immune tolerance therapy is costly, time consuming, and often requires placement of a central venous catheter.[59] Once achieved, however, immune tolerance facilitates the management of bleeding episodes with specific factor replacement therapy. Rituximab, an anti-CD20 monoclonal antibody, has been used with some success in a few patients with acquired factor VIII inhibitors.[60] The mechanism of action involves the rapid depletion of circulating B cells, which produce antibodies, including the anti–factor VIII antibody. An ongoing clinical trial is assessing the use of rituximab in patients with hemophilia and inhibitors who have previously failed immune tolerance.

Figure 110–3 summarizes the therapeutic options in the management of hemophilia A patients with inhibitors. The same algorithm can be applied to the management of hemophilia B patients, except that factor IX should be substituted for factor VIII. Use of porcine factor VIII is not indicated for inhibitors in hemophilia B.

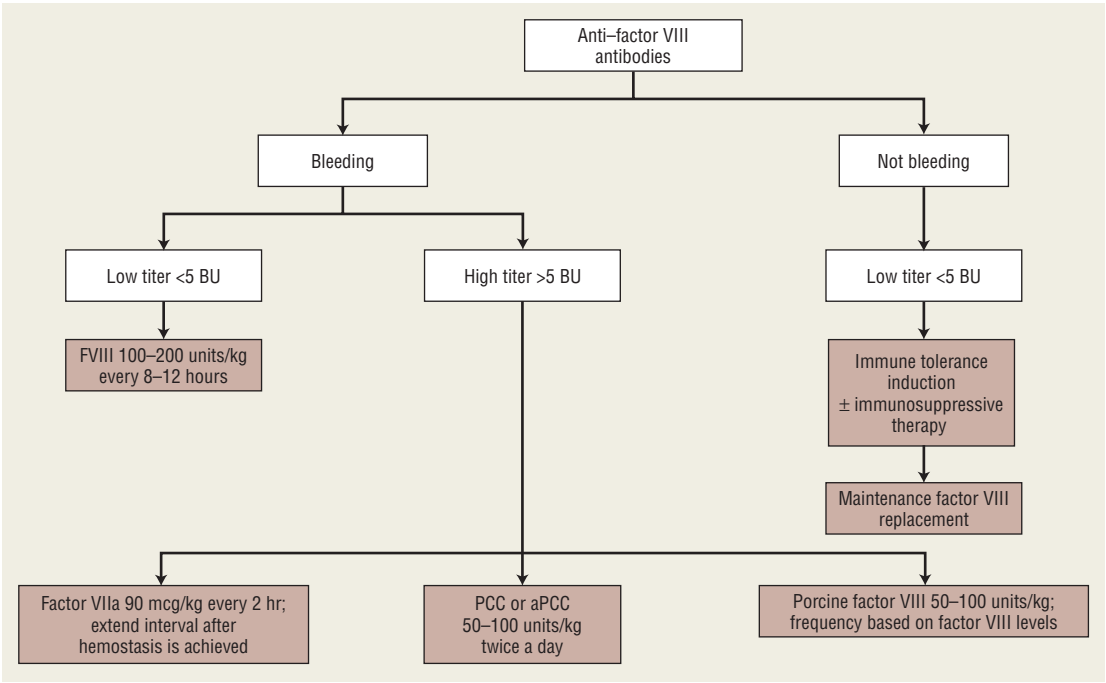

FIGURE 110-3. Treatment algorithm for the management of patients with hemophilia A and factor VIII antibodies. (aPCC, activated prothrombin complex concentrate; BU, Bethesda unit; PCC, prothrombin complex concentrate.)

GENE THERAPY IN HEMOPHILIA

Use of gene therapy for hemophilia A and B is currently under investigation and continues to face significant challenges. A number of different viral and nonviral vectors have been used to transfer the recombinant factor gene to human cells, such as liver and muscle cells.[61] Even low levels of factor expression through gene therapy should reduce bleeding episodes in patients with severe hemophilia, a rationale for gene therapy similar to that for prophylactic factor replacement. Furthermore, given the broad range of physiologically normal factor levels, very tight regulation of gene expression is not necessary. The safety and efficacy of this approach to treatment remain to be determined. A total of five clinical trials have been completed but none have had significant enough results to progress to phase III clinical studies.[61] Potential benefits to gene therapy include patient convenience, viral safety, and decreased cost. Possible drawbacks to gene therapy include a risk of inhibitor formation, tumorigenesis related to integration of the viral vector, possible germ-line transmission, and concerns about long-term gene expression.[62]

PAIN MANAGEMENT IN HEMOPHILIA

Pain, both acute and chronic, can be a common occurrence in patients with hemophilia. The likely cause of acute pain is bleeding, and control of the bleeding episode should ease the pain. Chronic pain may be the result of permanent joint changes. Surgical intervention may help to alleviate the pain, as may an intensive physical therapy program.[63] Intraarticular administration of dexamethasone may also be useful.[64] Acetaminophen can be used, although narcotic analgesia may be required for more severe pain. Nonsteroidal antiinflammatory drugs impair platelet function and may increase the risk of bleeding in patients with hemophilia, although these drugs have been used for the management of chronic arthropathy. Cyclooxygenase-2 inhibitors have less antiplatelet activity and may be an option for pain management.

SURGERY IN HEMOPHILIA

In the patient with hemophilia undergoing a surgical procedure, the goal of treatment is maintaining factor levels of at least 0.5 to 0.7 units/mL (50%–70%) during surgery and in the postoperative period in order to prevent excessive bleeding. Intermittent dosing or continuous infusion factor replacement may accomplish this goal. Before surgery, factor concentrate is usually infused to obtain a plasma level of 1 unit/mL (100%). Replacement therapy is continued to maintain plasma levels greater than 0.5 units/mL (50%) for 5 to 7 days or longer, depending on the type of surgery. Preoperative evaluation for elective procedures should include measurement of an inhibitor titer and assessment of the recovery and half-life of infused factor in the patient. Elective surgery should not proceed unless therapeutic plasma levels can be obtained.

Evaluation of Therapeutic Outcomes

The main goal in the treatment of hemophilia is controlling and preventing bleeding episodes and their long-term sequelae, such as chronic arthropathies. Pharmacologic and nonpharmacologic interventions should be aimed at achieving this goal. Treatment response can be monitored through clinical parameters, such as cessation of bleeding and resolution of symptoms. Determination of plasma factor levels may also be helpful, particularly for severe bleeding episodes. Home therapy for administration of factor concentrates is common among these patients because this approach can lead to earlier treatment and more independence for the patient. Diaries in which the patient documents symptoms, the dose of factor replacement, adjuvant therapies used, and treatment response can help the caregiver evaluate the success of home therapy. Monitoring the number and type of bleeding episodes and measuring trough plasma factor levels make it possible to evaluate the adequacy of prophylactic regimens. Physical examination with evaluation of joint range of motion and radiographs of target joints indicates the long-term success of preventing and treating arthropathies.

TABLE 110-6 Von Willebrand Disease

von Willebrand factor (vWF)
Large multimeric glycoprotein that is necessary for normal platelet adhesion, normal bleeding time, and stabilizing factor VIII.

von Willebrand factor antigen (vWF:Ag)
Antigenic determinant(s) on vWF measured by immunoassays; usually low in types 1 and 2; virtually absent in type 3.

Ristocetin cofactor activity
Functional assay of vWF activity based on platelet aggregation with ristocetin. Reduced by the same degree as vWF:Ag in types 1 and 3, but to a greater extent in type 2 disease (except 2B).

Clinicians should check for the development of inhibitors, especially in patients with severe disease and exposure to factor concentrates, at least yearly and with any suspicion of poor treatment response. The development of inhibitors challenges the management and control of bleeding episodes. A full understanding of the clinical situation and the titer of the inhibitor are mandatory to address all treatment options for each patient. Because no laboratory test measures the effectiveness of therapy in this scenario, close clinical monitoring for worsening or resolution of symptoms is essential for optimizing the outcome.

VON WILLEBRAND DISEASE

The most common congenital bleeding disorder in the United States and in the world, von Willebrand disease, has a prevalence of 1% to 2%.[65] Von Willebrand disease refers to a family of disorders caused by a quantitative and/or qualitative defect of von Willebrand factor, a glycoprotein that plays a role in both platelet aggregation and coagulation (Table 110–6). Unlike hemophilia, von Willebrand disease has an autosomal inheritance pattern, resulting in an equal frequency of disease in males and females.

The gene for von Willebrand factor is located on chromosome 12 and is 178 kb in length.[66,67] Transcription and translation produce a large primary product that subsequently undergoes complex modifications, resulting in von Willebrand factor multimers of various sizes with molecular weights ranging from 500 to 20,000 kDa. Von Willebrand factor is synthesized in endothelial cells, where it is either stored in Weibel-Palade bodies or secreted constitutively.[68] It is also synthesized in megakaryocytes and stored in α-granules, from which it is released following platelet activation.

Von Willebrand factor is important for both primary and secondary hemostasis. In response to vascular injury, it promotes platelet adhesion by interacting with the glycoprotein Ib receptor on platelets.[66,68] It can facilitate platelet aggregation by binding to the platelet glycoprotein IIb/IIIa receptor, although fibrinogen is the main ligand for this receptor.[66] The highest-molecular-weight von Willebrand factor multimers appear to be the most important in platelet adhesion because their large surface area contains numerous binding sites for various ligands and receptors. An additional function of von Willebrand factor is that it is the carrier molecule for circulating factor VIII, protecting it from premature degradation and removal.[69] A deficiency of von Willebrand factor reduces the half-life of factor VIII and decreases plasma factor VIII levels. Therefore, von Willebrand factor plays a dual role in hemostasis, affecting both platelet function and coagulation.

Classification of von Willebrand Disease

Von Willebrand disease consists of a heterogeneous group of disorders that can be classified into three major subtypes. The NIH has developed a classification scheme that characterizes von Willebrand disease according to both the quantity of the von Willebrand clotting factors and their functionality (Table 110–7). Types 1 and 3 are associated with quantitative defects in von Willebrand factor; type 2 mutations refer to functional abnormalities in von Willebrand factor.[70] Determination of the disease subtype is important because it influences treatment.

Type 1 von Willebrand disease is the most common type, accounting for 75% of cases.[65] It is characterized by a mild-to-moderate reduction in the level of von Willebrand factor (although its multimeric structure is normal) and a similar reduction in the level of factor VIII. It is usually inherited in an autosomal dominant fashion with variable penetrance and expression.[71] Bleeding symptoms are often very mild to moderate.[69] Patients with von Willebrand disease can experience easy bruising, nosebleeds, or other mucosal bleeding such as gastrointestinal or heavy menstrual bleeding. Subjects may be at risk of bleeding following surgery, traumatic injury, or childbirth.[65]

Type 2 von Willebrand disease, diagnosed in 9% to 30% of affected patients, is characterized by a qualitative abnormality of von Willebrand factor.[69] Bleeding manifestations may be more severe than with type 1 disease. Inheritance is most often autosomal dominant but may be recessive.[71] Type 2 von Willebrand disease can be subdivided into four variants. Type 2A is the most frequent subtype and is characterized by a reduced von Willebrand factor–platelet interaction and an absence of high- and intermediate-molecular-weight factor multimers. Type 2B is a less common variant characterized by an abnormal von Willebrand factor that has an increased affinity for the platelet glycoprotein Ib receptor. This is associated with thrombocytopenia, which is usually mild. In addition, there is usually an absence of high-molecular-weight forms of von Willebrand factor. Type 2M arises from a qualitative defect in von Willebrand factor that impairs its binding to platelets; it is similar to type 2A, except that there is no measurable reduction in the high-molecular-weight multimers.[71] Finally, type 2N von Willebrand disease (Normandy) is a rare form of the disease in which von Willebrand factor has a markedly reduced affinity for factor VIII. This leads to a moderate-to-severe reduction of factor VIII plasma levels with normal von Willebrand factor levels.[71]

TABLE 110-7 VWD Classification and Laboratory Values

Condition	Description	VWF-RCo (IU/dL)	VWF-Ag (IU/DL)	FVIII	VWF-RCo/VWF-Ag Ratio
Type 1	Partial quantitative VWF deficiency	<30	<30	↓or Normal	>0.5–0.7
Type 2A	↓VWF-dependent platelet adhesion with selective deficiency of high-MW VWF multimer	<30	<30–200	↓or Normal	<0.5–0.7
Type 2B	↑VWF affinity for platelet GP Ib; ± ↓platelet numbers	<30	<30–200	↓or Normal	Usually <0.5–0.7
Type 2M	↑VWF-dependent platelet adhesion without selective deficiency of high-MW VWF multimers	<30	<30–200	↓ or Normal	<0.5–0.7
Type 2N	Markedly ↓VWF binding affinity for FVIII	30–200	30–200	↓↓	>0.5–0.7
Type 3	Virtually complete deficiency of VWF	<3	<3	↓↓↓(<10 IU/dL)	Not applicable
"Low VWF"		30–50	30–50	Normal	>0.5–0.7
Normal		50–200	50–200	Normal	>0.5–0.7

(Modified from Reference A.)

TABLE 110-8 Questions to Ask Patient

1. Have you or a blood relative ever needed medical attention for a bleeding problem or been told you have a bleeding disorder or problem?
   - During or after surgery?
   - With dental procedures or extractions?
   - During childbirth or for heavy menses?
   - Ever had bruises with lungs?
2. Do you have or have you ever had:
   - Liver or kidney disease?
   - A blood or bone marrow disorder?
   - A high or low platelet count?
3. Do you take aspirin, NSAID, clopidogrel, warfarin, or heparin?

If yes to any of the above questions, ask additional questions:

1. Do you have a blood relative who has a bleeding disorder, such as von Willebrand disease or hemophilia?
2. Have you ever had prolong bleeding from trivial wounds, lasting more than 15 minutes or recurring spontaneously during the 7 days after the wound?
3. Have you ever had heavy, prolonged, or recurrent bleeding after surgical procedures, such as tonsillectomy?
4. Have you ever had bruising, with minimal or no apparent trauma, especially if you could feel a lump under the bruise?
5. Have you ever had a spontaneous nosebleed that required more than 10 minutes to stop or needed medical attention?
6. Have you ever had heavy, prolonged, or recurrent bleeding after dental extractions that required medical attention?
7. Have you ever had blood in your stool, unexplained by a specific anatomic lesion (such as an ulcer in the stomach or polyp in the colon), that required medical attention?
8. Have you ever had anemia requiring treatment or received a blood transfusion?
9. For women, have you ever had heavy menses, characterized by the presence of clots greater than an inch in diameter and/or changing a pad or tampon more than hourly or resulting in anemia or low iron level?

(Adapted from the National Heart, Lung, and Blood Institute Expert Panel for Assessment of VWD. Reference 65.)
NSAID, non-steroidal antiinflammatory drug.

Type 3 von Willebrand disease refers to a severe quantitative variant of the disease in which von Willebrand factor is nearly undetectable and factor VIII levels are very low. It is often inherited in an autosomal recessive fashion.[69] Type 3 von Willebrand disease is rare, affecting only about 1 person in 1,000,000.[65] The clinical phenotype is severe, reflecting major deficits in primary hemostasis and coagulation.

There is a platelet-type pseudo–von Willebrand disease in which von Willebrand factor is normal but a defect in the platelet glycoprotein Ib receptor causes an increased affinity for normal von Willebrand factor.[69] As a result, platelet-type pseudo–von Willebrand disease is phenotypically similar to type 2B disease but should be distinguished from it because the treatment is different.

Acquired von Willebrand disease is a rare bleeding disorder that is similar to the congenital form of the disease. It has been reported primarily in association with autoimmune disorders, such as systemic lupus erythematosus, lymphoproliferative disorders, myeloproliferative disorders, hypothyroidism, and certain neoplastic diseases such as Wilms tumor and lymphoma.[69,72] It has been reported in situations of high shear stress, such as aortic stenosis. Certain medications have been associated with acquired von Willebrand disease, including valproic acid, griseofulvin, hydroxyethyl starch, and ciprofloxacin.[72] Bleeding manifestations vary from mild to severe, and the condition often resolves with treatment of the underlying disease. Various mechanisms have been proposed, including autoantibodies to von Willebrand factor resulting in rapid removal from the plasma, adsorption to tumor cells or activated platelets, increased proteolysis, or mechanical destruction.[72]

CLINICAL PRESENTATION OF VON WILLEBRAND DISEASE

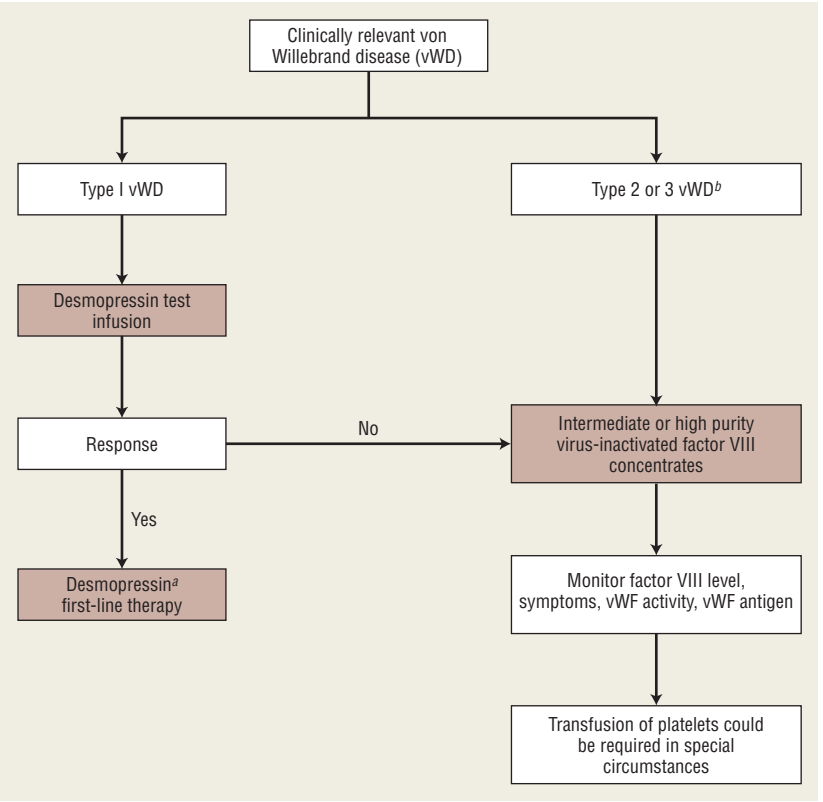
- Clinical manifestations are variable; some patients are asymptomatic.
- Mucocutaneous bleeding: epistaxis, gingival bleeding with minor manipulation, menorrhagia
- Easy bruising
- Postoperative bleeding

Diagnosis

When a patient has a lifelong history of mucocutaneous bleeding and a family history of abnormal bleeding, the clinician should suspect von Willebrand disease. For a review of clinical questions to ask the patient, refer to the National Heart, Lung, and Blood Institute (NHLBI) guidelines (Table 110–8).[65] Several different laboratory tests are helpful in the diagnosis of this hemostatic abnormality. Initial screening tests include determinations of PT, aPTT, and platelet count. PT is normal, whereas aPTT may be normal or prolonged in relation to the reduction in plasma factor VIII levels. A normal aPTT does not rule out von Willebrand disease; specific laboratory assessment of the von Willebrand factor is required. The platelet count is usually is normal, although thrombocytopenia is common in type 2B and platelet-type pseudo–von Willebrand disease. The bleeding time or PFA-100 may be prolonged but can be normal in patients with milder forms of the disease.

Specific laboratory tests for determining the presence of von Willebrand disease include measurement of von Willebrand factor antigen (vWF:Ag) level, factor VIII assay, determination of von Willebrand factor (ristocetin cofactor) activity, and von Willebrand factor multimer analysis (see Table 110–6). Plasma concentrations of von Willebrand factor increase with age, cigarette smoking, exercise, pregnancy starting in the second trimester, and infection, as well as with use of certain medications, such as corticosteroids, high-dose estrogen birth control pills, and desmopressin.[73] Repeated test measurements may be necessary to make the diagnosis because of physiologic variations in plasma levels.

Electroimmunoassay, immunoradiometric assay, or enzyme-linked immunosorbent assay can be used to quantify vWF:Ag.[69] vWF:Ag levels are known to vary with different ABO blood types.[74] The vWF:Ag level is usually low in types 1 and 2 von Willebrand disease and virtually absent in type 3 disease. Factor VIII levels are normal or mildly decreased in patients with type 1 or 2 disease and very low (<10%) in those with type 3 disease.[69] Ristocetin, an antibiotic that causes platelet aggregation in the presence of functional von Willebrand factor, is used to measure von Willebrand factor activity. The assay is performed by mixing platelet-free patient plasma, normal formalin-fixed platelets, and ristocetin and then quantitating the extent of platelet agglutination. Ristocetin cofactor activity is usually reduced in parallel to vWF:Ag levels in types



[a]Use factor VIII concentrate for life-threatening bleeding.
[b]Some patients with type 2 or 3 von Willebrand disease may respond to desmopressin.

FIGURE 110-4. Guidelines for treatment of von Willebrand disease.

1 and 3 disease and decreased to a greater extent than vWF:Ag in type 2 disease (except type 2B).[71] Ristocetin-induced platelet agglutination is useful for further distinguishing type 2B disease, as a low concentration of ristocetin induces excessive aggregation in type 2B disease. The reader is referred to Table 110–7 for a summary of the various types of von Willebrand disease.

Von Willebrand factor multimers can be analyzed by separating them by size on an agarose gel. All multimer sizes are present in type 1 disease, whereas reduced levels of intermediate- and high-molecular-weight multimers are characteristic of type 2 disease. Type 3 patients lack all types of von Willebrand factor multimers.

The von Willebrand factor gene was cloned in the mid-1980s, and now the role of molecular genetics is coming into play in the diagnosing of von Willebrand disease. Molecular genetic testing for von Willebrand disease is now a feasible option in some instances.[75] Genetic testing may be used to clarify diagnostic uncertainty that may remain after coagulation testing and clinical evaluation.

TREATMENT

von Willebrand Disease

4 The specific type of von Willebrand disease, as well as the location and severity of bleeding, determines the approach to treatment. Local measures, including pressure, ice, and topical thrombin, can often control superficial bleeding. Systemic treatment is used for bleeding that cannot be controlled in this manner and for prevention of bleeding with surgery. The goal of systemic therapy is correction of platelet adhesion and coagulation defects by stimulating the release of endogenous von Willebrand factor or by administering products that contain von Willebrand factor and factor VIII.[68] General guidelines for treatment of von Willebrand disease are shown in Figure 110–4. The von Willebrand disease guidelines are available at the NHLBI Web site (http://www.nhlbi.nih.gov/guidelines/vwd/index.htm). In addition, a consensus guideline for the treatment of von Willebrand disease and other bleeding disorders in women was published in 2009.[76]

REPLACEMENT THERAPY

5 The treatment of choice for patients with types 2B, 2M, and 3 von Willebrand disease and for patients with type 1 or 2A von Willebrand disease who are unresponsive to desmopressin (which is discussed in the next section) is replacement therapy with plasma-derived von Willebrand factor–containing products.[77] Several virus-inactivated, intermediate- or high-purity factor VIII concentrates contain sufficient amounts of functional von Willebrand factor.[77] Humate-P is a lyophilized, pasteurized, VWF/FVIII complex (human) that contains the high-molecular-weight multimers of von Willebrand factor.[78] Ultrahigh-purity (monoclonal antibody-derived) plasma-derived products and recombinant factor VIII products contain only negligible amounts of von Willebrand factor and are inadequate for treatment of von Willebrand disease. A very high purity plasma-derived von Willebrand factor concentrate and a recombinant von Willebrand factor product are currently in clinical trials.[79] Because these von Willebrand factor concentrates do not contain appreciable factor VIII, concomitant administration of a factor VIII–containing product may be necessary for patients with severe disease and low levels of factor VIII.[80] Cryoprecipitate contains approximately 80 to 100 units of von Willebrand factor per unit (5–10 times more von Willebrand factor and factor VIII than fresh-frozen plasma), and in the past it was the mainstay of therapy

TABLE 110-9 Replacement Therapy in von Willebrand Disease[a]

Condition	Therapy
Major surgery	Maintain factor VIII level ≥50% for 1 week Prolonged treatment in type 3 patients (>7 days)
Minor surgery	Maintain factor VIII level ≥50% for 1–3 days Maintain factor VIII level >20%–30% for an additional 4–7 days
Dental extraction	Single infusion to achieve factor VIII level >50% Desmopressin prior to procedure for type I
Spontaneous or posttraumatic bleeding	Usually single infusion of 20–40 units/kg

[a]The yield of factor VIII after first infusion is similar to that observed in hemophilia A (about 2% increment over baseline amount for every 1 unit/kg of factor VIII infused).

for von Willebrand disease.[69] However, because cryoprecipitate is not virally inactivated, it should not be used as first-line treatment. General guidelines for the dosing of replacement therapy in patients with von Willebrand disease unresponsive to desmopressin are provided in Table 110–9.

OTHER PHARMACOLOGIC THERAPY

6 Desmopressin stimulates the endothelial cell release of von Willebrand factor and factor VIII. It is effective for patients with von Willebrand disease who have adequate endogenous stores of functional von Willebrand factor. This group includes most patients with type 1 disease and some patients with type 2A disease. Conversely, desmopressin is not appropriate for patients with type 3 disease, who lack stores of von Willebrand factor.

CLINICAL CONTROVERSY

Some hematologists find desmopressin beneficial in treating patients with type 2B von Willebrand disease, whereas others believe it may exacerbate thrombocytopenia.

Desmopressin is not usually recommended for treatment of type 2B disease because the release of additional abnormal von Willebrand factor may exacerbate thrombocytopenia.[69] However, desmopressin has been reported to be beneficial in some patients with type 2B disease.[69] If desmopressin is used for treatment of type 2B disease, close monitoring is necessary.

The dose of desmopressin used for treatment of von Willebrand disease is identical to that used for treatment of mild factor VIII deficiency, 0.3 mcg/kg diluted in 30 to 50 mL of normal saline and given intravenously over 15 to 30 minutes. In general, patients with von Willebrand disease have a better response to desmopressin than those with hemophilia, with an average threefold to fivefold rise in von Willebrand factor and factor VIII levels.[69] These levels remain elevated for approximately 6 to 8 hours. The response to desmopressin in a given patient is usually consistent, and a trial of desmopressin should establish if the medication will likely be effective for the individual. Desmopressin is preferable to use of plasma-derived products for patients who have an adequate response because desmopressin does not carry a risk of viral transmission. An added benefit is the substantially lower cost of desmopressin compared with the plasma-derived products. (For a discussion of the side effects of desmopressin, see earlier Treatment of Hemophilia A.)

Desmopressin can be administered every 12 to 24 hours, but the response diminishes with repeated treatment. After three to four doses, desmopressin is often no longer effective, and alternative replacement therapy may be necessary if prolonged treatment is required. Laboratory monitoring, including vWF:Ag measurements, factor VIII assays, vWF:activity assessments, and clinical examinations, will determine the adequacy of treatment.

Intranasal administration of desmopressin at the same dosage as that used for mild factor VIII deficiency can be useful for treatment of mild bleeding episodes. One or two doses administered at the start of menses may be helpful in controlling menorrhagia.[81] Oral contraceptives may also be very effective in controlling this symptom. Antifibrinolytic agents, such as aminocaproic acid and tranexamic acid, may be of special value in tissues rich in plasminogen activators, such as the mouth, especially with tooth extractions.[69] They can also be used in the management of epistaxis, gastrointestinal bleeding, and menorrhagia. However, these agents should be avoided in urinary tract bleeding because of the risk of thrombosis and obstruction.

In acquired von Willebrand disease, low levels of plasma von Willebrand factor are the result of accelerated removal of protein from plasma through the action of different pathogenic mechanisms. Acquired von Willebrand disease may be associated with monoclonal gammopathy, lymphoproliferative or myeloproliferative syndromes, or cardiovascular disease. The treatment of the underlying lymphoproliferative disease with rituximab, a monoclonal antibody against CD-20 on lymphocytes, has been reported to be relatively ineffective in the management of the acquired von Willebrand disease.[82] Therefore, intravenous gammaglobulin remains an additional therapy in acquired von Willebrand disease, along with von Willebrand factor concentrate and/or desmopressin.

GENE THERAPY

Patients with the most severe bleeding phenotypes of von Willebrand disease (type 3 and some severe cases of types 1 and 2) may be the most likely candidates for gene therapy, which may offer the potential of a long-term, if not lifelong, correction of von Willebrand factor deficiency. Studies placing von Willebrand factor cDNA into a lentiviral vector are currently ongoing.[67] Preclinical trials are being conducted to test the feasibility of gene transfer to be utilized in the management of von Willebrand disease.

OTHER CONGENITAL FACTOR DEFICIENCIES

In addition to deficiencies in factors VIII and IX, congenital deficiencies in fibrinogen, in factors II, V, VII, X, XI, and XIII, and in combinations of factor deficiencies have been reported.[83] Contact factor abnormalities, including deficiencies in factor XII, high-molecular-weight kininogen, and prekallikrein, prolong the aPTT but do not lead to any bleeding diathesis. Identification of these disorders is important so that inappropriate treatment is not given. The only contact factor deficiency associated with bleeding symptoms is factor XI deficiency. Also known as hemophilia C, this deficiency is particularly common in people of Ashkenazi Jewish descent.[83] Bleeding manifestations are variable. Bleeding does not usually occur spontaneously, but excessive bleeding may occur after trauma or surgery. Most other deficiencies are inherited as autosomal recessive disorders and are rare. Some patients with abnormal molecules, such as a dysfibrinogenemia, may have an increased tendency to develop thromboembolic disease. Most of these deficiencies are treated with fresh-frozen plasma. Newer specific concentrates are becoming available. For example, a factor XIII plasma-derived concentrate is available, and recombinant factor VIIa is approved for use in patients with congenital VII deficiency. Cryoprecipitate, which is rich in fibrinogen, can be used to treat patients with fibrinogen deficiency or dysfunctional fibrinogen (dysfibrinogenemia).

COMPLICATIONS OF REPLACEMENT THERAPY

Transmission of bloodborne infectious diseases is always a concern when blood and blood-derived products are used. Most patients with hemophilia who received plasma-derived products were infected with hepatitis viruses and HIV during the 1980s prompting the development of viral inactivation methods for use during the manufacturing of factor concentrates.[29] All currently available plasma-derived factor concentrates come from screened donors and undergo viral inactivation procedures in an effort to reduce the risk of viral transmission. Heat treatment, which includes dry and wet heat, is one method of viral inactivation. Wet heat is applied while the concentrate is in suspension or in solution (pasteurization) and appears to be more effective than dry heat. Other methods of viral inactivation include chemical (solvent detergent) and affinity chromatography with monoclonal antibodies. Solvent detergent treatment inactivates lipid-coated viruses such as HIV and hepatitis B and C, but it is not effective against parvovirus B19, transfusion transmitted virus, hepatitis A, or prions.[29] Parvovirus B19 has been found in both plasma-derived and recombinant factor VIII concentrates (due to the use of albumin as a stabilizer in some recombinant products).[29,30] Parvovirus B19, may be particularly important for patients with hemophilia and HIV infection because it can cause chronic anemia in patients with immune deficiency.[23] Concern has arisen as prions are not inactivated by either solvent detergent treatment or heat, so there is a risk of transmission.[29]

Other complications associated with factor administration include allergic reactions, fever, chills, urticaria, and nausea. PCCs and aPCCs also have the potential to cause thromboembolic complications, including deep-vein thrombosis, pulmonary embolism, myocardial infarction, and DIC, likely related to the presence of activated factors.[14] Antifibrinolytic agents should not be given to patients receiving PCCs or aPCCs to avoid thrombotic complications.

Porcine factor VIII, used in the treatment of patients with inhibitors to factor VIII, is not known to transmit human viruses. However, allergic-type reactions (e.g., fever, chills, skin rashes, nausea, and headaches) have been reported.[54] Patients who experience these reactions can be treated with steroids and/or diphenhydramine. Thrombocytopenia is another potential complication of porcine factor VIII use.[54]

Recombinant factor VIII or IX has a low risk of viral transmission. Adverse effects of these products include metallic taste, mild dizziness, mild rash, burning at the infusion site, and a small drop in blood pressure.

PHARMACOECONOMIC CONSIDERATIONS

Treatment of severe hemophilia is often expensive, with a substantial portion of the cost related to the expense of factor concentrates. The highly purified plasma-derived products and recombinant factor concentrates are considerably more expensive than the low- and intermediate-purity products. However, the viral safety of recombinant products must be weighed against the added cost. Recombinant products are often used, particularly for children with hemophilia. With the widespread use of prophylactic factor replacement regimens to prevent chronic arthropathy, factor usage and cost of treatment have increased over those for on-demand therapy.[14] The positive impact on patient lifestyle must be weighed against the drawbacks of cost, the potential need for permanent venous access, and patient compliance. Finally, the use of immune tolerance therapy is associated with extremely high factor usage and cost, but with the potential benefit of eradicating an inhibitor, a life-threatening complication of hemophilia.

Optimal management of von Willebrand disease starts with adequate identification of the patient's disease type. Desmopressin is considerably less expensive than plasma-derived factor VIII concentrates.[69] It should be the treatment of choice for all patients responsive to the test dose because of its viral safety, reduced cost, and ease of administration.

ACQUIRED COAGULATION DISORDERS

DISSEMINATED INTRAVASCULAR COAGULATION

Systemic inflammation is associated with systemic activation of coagulation. The most severe variant of this is disseminated intravascular coagulation (DIC). Systemic activation of coagulation may be the result of cytokine release as part of an inflammatory response or due to the release of, or exposure to, procoagulant substances. DIC leads to fibrin clot formation in the microvasculature, often with compensatory bleeding owing to consumption of coagulation factors and platelets. Although the causes for DIC can be diverse (see Table 110–10), the pathophysiology leading to DIC is the same once the triggering event occurs (Fig. 110–5). An overwhelming insult leads to the formation of thrombin and plasmin beyond the control of the regulatory systems. Once formed, thrombin leads to the cleavage of fibrinopeptide A and B from fibrinogen, leaving a fibrin monomer. The monomer polymerizes into a clot, leading to microvascular and macrovascular thrombosis while consuming platelets by trapping them in the clots. Thrombosis ultimately decreases blood flow to multiple organs, leading to organ damage. Plasmin cleaves fibrinogen into fibrin(ogen) degradation products (FDPs), which can combine with the fibrin monomer before polymerization. This forms a soluble fibrin monomer that impairs hemostasis and leads to hemorrhage. Some of the FDPs may adhere to platelets, causing platelet dysfunction that may contribute to clinically significant hemorrhage. In addition, plasmin is a proteolytic enzyme that can degrade factors V, VIII, IX, and XI and other plasma proteins. Circulation of plasmin can activate the complement system, leading to red blood cell and platelet lysis. The activated complement system also increases vascular permeability that can cause hypotension and shock.

Complicating this process is an intricate web of feedback systems. Thrombin induces activation of factors V and XI, while it also activates protein C that inhibits the activation of the same. Antithrombin is a serine protease that mediates the antithrombotic effect of heparin. It also inhibits the activation of thrombin, plasmin, and factors IXa, Xa, XIa, and XIIa.[80] Acute DIC is characterized by rapid and extensive depletion of coagulation factors and inhibitors and excessive fibrinolysis in an attempt to compensate for microvascular clotting. Normally, a balanced dynamic process of clotting and fibrinolysis operates to prevent organ dysfunction, bleeding, or clotting. In acute DIC, excessive intravascular coagulation overcomes the normal inhibitory processes. In subacute or chronic DIC, the balance between depletion and synthesis of coagulation factors in the circulation may make the diagnosis difficult, because patients may be asymptomatic. Thrombosis predominates over bleeding in chronic DIC.[1]

In summary, bleeding problems observed during DIC can be the result of consumption of coagulation factors during clotting, depletion or dysfunction of platelets, interference in fibrin formation by FDPs, and lysis of clots by plasmin. Thrombosis occurs in parallel with the bleeding process, and the extent of microvascular obstruction will determine the degree of organ damage.

TABLE 110-10 Conditions Associated with Disseminated Intravascular Coagulation

Cardiovascular
Acute myocardial infarction
Angiopathy
Aortic aneurysm
Aortic balloon assist devices
Giant hemangiomas
Peripheral vascular disease
Postcardiac arrest
Prosthetic devices
Raynaud syndrome
Infectious
Arbovirus
Aspergillus
Candida albicans
Cytomegalovirus
Ebola virus
Gram-negative bacteria
Gram-positive bacteria
Herpesvirus
Histoplasma
Human immunodeficiency virus
Influenza
Kala-azar
Malaria
Mycobacteria
Mycoplasma
Paramyxoviruses
Rocky Mountain spotted fever
Rubella
Typhoid
Varicella
Variola

Intravascular hemolysis
Hemolytic transfusion reaction
Hemolytic uremic syndrome
Minor hemolysis
Massive transfusion
Newborn
Birth asphyxia
Hypothermia
Meconium or amniotic fluid aspiration
Necrotizing enterocolitis
Respiratory distress syndrome
Shock
Obstetrics
Abortion
Amniotic fluid embolism
Fatty liver of pregnancy
Placental abruption
Preeclampsia/eclampsia
Retained fetus syndrome
Pulmonary
Acute respiratory distress syndrome
Empyema
Hyaline membrane disease
Pulmonary embolism
Pulmonary infarction
Tissue injury
Burns
Crush injuries
Extensive surgery
Head trauma
Multiple trauma

Miscellaneous
Acid–base imbalance
Acute liver failure
Amphetamines
Anaphylaxis
Autoimmune diseases
Cholestasis
Chronic inflammatory diseases
Collagen vascular disease
Craniotomy
Extracorporeal circulation
Extracorporeal membrane oxygenation
Fat embolism
Heat stroke
Hemorrhagic telangiectasia
Hepatitis
Leukemia
Lightning strikes
Near drowning
Organic solvent poisoning
Paroxysmal nocturnal hemoglobinuria
Peritoneovenous or pleurovenous shunts
Polycythemia rubra vera
Renal vascular disorders
Severe anoxia
Snake bite
Solid tumors
Transplant rejection

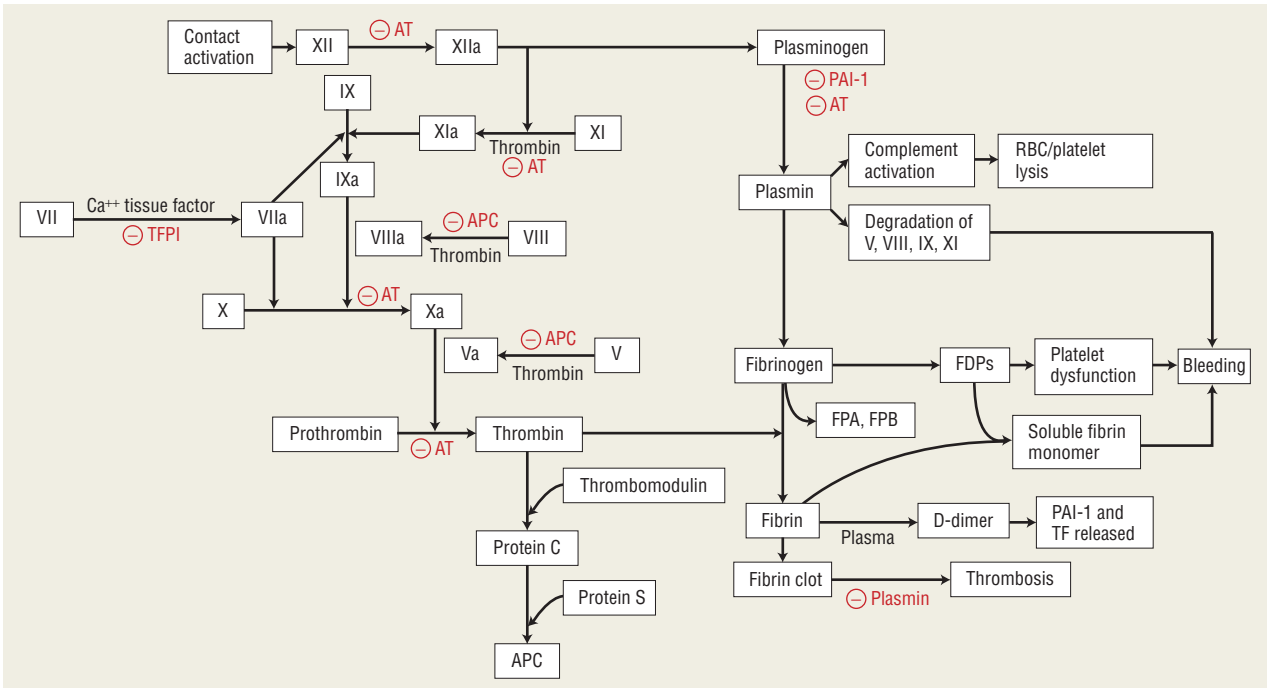


FIGURE 110-5. Pathophysiology of disseminated intravascular coagulation. (APC, activated protein C; AT, antithrombin; FDP, fibrin degradation product; FPA, fibrinopeptide A; FPB, fibrinopeptide B; PAI-1, plasminogen activator inhibitor type 1; RBC, red blood cell; TFPI, tissue factor pathway inhibitor.)

CLINICAL PRESENTATION OF DISSEMINATED INTRAVASCULAR COAGULATION

General

- Underlying illness (Table 110–10)

Signs and Symptoms

- Bleeding, thrombosis, or both
- Petechiae and purpura
- Peripheral cyanosis
- Hemorrhagic bullae

Laboratory Tests

- Elevated D-dimer
- Decreased antithrombin
- Decreased fibrinogen
- Thrombocytopenia
- Decreased proteins C and S
- Increased fibrinopeptides A and B
- Elevated prothrombin fragments 1 and 2
- Evidence of end-organ dysfunction or failure

Laboratory Diagnosis

No single laboratory test has adequate sensitivity and specificity to confirm or exclude a diagnosis of DIC. PT, aPTT, and platelet count are used to screen for hemostatic function and indirectly evaluate the degree of coagulation factor consumption and activation. The most common laboratory abnormalities in decreasing order of frequency are: thrombocytopenia, elevated FDP, prolonged PT, prolonged aPTT, and low fibrinogen.[84]

Thrombocytopenia is a sensitive, but not specific, sign of DIC.[84] It is present in up to 98% of DIC cases. Thrombin-induced platelet aggregation is the leading cause of platelet consumption.[84] In the absence of thrombocytopenia, a continuous decline in platelet count may indicate active thrombin generation.

The extent of fibrin formation is indirectly assessed by measuring the byproducts of its lysis, such as FDP or D-dimer. These are measures of fibrinolytic activity and not specific to DIC. Because FDPs are metabolized in the liver and secreted by the kidney, organ damage may increase the level of FDPs. However, an increased FDP level may help to identify compensated DIC, as it may be the only abnormal laboratory result. D-dimer is formed when plasmin digests cross-linked fibrin; thus the level of D-dimer is a more specific measure of FDPs.

PT and aPTT are prolonged in 50% to 60% of cases, but they may be decreased or normal.[84] These times may be normal or shorter due to circulating activated clotting factors that accelerate thrombin formation. Fibrinogen is an acute-phase reactant and may remain in the normal range despite ongoing consumption. A low level indicates DIC with only 28% sensitivity.[84] Depressed levels of antithrombin, protein C, and protein S are seen in most patients. Severe initial decreases in antithrombin levels occur in septic DIC. Activity levels below 50% to 60% correlate with poor outcome.[80]

The Scientific and Standardisation Committee on DIC of the International Society on Thrombosis and Haemostasis developed a scoring system for overt DIC.[84,85] The scoring system is based on routine coagulation tests. The scoring system is only valid if the patient has an underlying condition associated with DIC. The committee has suggested that the score not be used in patients with liver failure or within the first 24 hours in trauma patients. One drawback to this score is that it is static and does not account for the dynamic coagulation changes in DIC. This score has been validated in children and adults and is sensitive for infectious and noninfectious etiologies. A strong correlation has been established between increasing score and mortality.[84,85]

The most commonly used fibrin-related markers for the DIC score are FDP and D-dimer. D-dimer assays are not standardized and the definition of elevated levels varies among the validation studies for the DIC score. In general, moderate increase has been defined as 2 to 5 times the upper limit of normal and a strong increase is greater than 5 to 10 times the upper limit of normal.

TREATMENT

Disseminated Intravascular Coagulation

7 If unrecognized and left untreated, DIC may lead to death as a result of hemorrhage or thrombosis. However, there is some controversy regarding optimal treatment because of the different mechanisms and clinical manifestations that can occur with DIC. Even so, there is a consensus that the most important step in therapy for DIC is treatment of the underlying disease.[84] In a pregnant woman with placental abruption or retained placenta in whom the disease is self-limited, delivery of the fetus with the products of conception usually returns hemostasis to normal. In patients who have overwhelming sepsis or shock, antibiotics and treatment of hypotension are the mainstays of therapy. In patients who are receiving maximum treatment for the underlying condition but in whom the process is worsening or in whom bleeding develops, additional treatments may be necessary.

The efficacy of fresh-frozen plasma or platelet transfusions has not been proven in randomized clinical trials but is rational for patients who are bleeding or require invasive procedures.[84] Fresh-frozen plasma replaces clotting factors, fibrinogen, protein S, protein C, and antithrombin. If hypofibrinogenemia is severe, cryoprecipitate may be useful as a concentrated source of fibrinogen. Although it has been argued that replacement of coagulation factors may worsen the situation, in practice this does not appear to make the situation worse, and it frequently improves hemostasis.

Trials of antithrombin concentrate in the treatment of DIC from various causes show some beneficial effect on improving DIC score, decreasing duration of DIC, or improving end-organ function. A large multicenter, randomized, controlled trial showed no significant decrease in mortality when used in septic patients but increased bleeding when antithrombin was given with heparin. A subset analysis showed a 14.6% decrease in 28-day mortality.[86] Due to variable efficacy and lack of prospective evidence showing an effect on mortality, recent practice guidelines recommend against its use.[84]

Anticoagulation in patients with DIC is controversial. The main pathogenic factor of DIC is considered to be the generation of intravascular thrombin. In patients where thrombosis predominates, heparin should be considered.[84]

CLINICAL CONTROVERSY

Heparin use in patients with disseminated intravascular coagulation may prevent the formation of new blood clots. The most common complication of heparin therapy is bleeding, so some clinicians find the risk too high to justify heparin use.

The main advantage of heparin is that it can prevent further thrombosis and consumption of hemostatic factors, but it has no

effect on an already established microthrombus within the vasculature. Because the major complication of heparin therapy is bleeding, some experts argue against heparin use in patients with an existing bleeding disorder. Although case reports have shown improvement in individual patients, heparin has not been shown to reduce morbidity or mortality in controlled clinical trials. Heparin rarely restores the coagulopathy to normal, although both the deficiency of coagulation factors and the thrombocytopenia may improve. If the patient does not respond to the replacement of coagulation factors, the addition of heparin may improve the coagulopathy by forming the heparin–antithrombin complex to inhibit thrombin.

Heparin may be given subcutaneously or as a continuous IV infusion. The dosage of heparin for DIC is controversial, ranging anywhere from full-dose to low-dose heparin. Full-dose heparin in adults requires administration of 5,000 units as an IV bolus, followed by a continuous infusion at 1,000 units per hour or according to a weight-based heparin dosing regimen. Some experts advocate low-dose heparin for patients at high risk of bleeding, such as an infusion of 10 units per kilogram per hour in adults.[84] Monitoring of heparin therapy is difficult because the aPTT is often elevated before initiation of heparin therapy, so following D-dimer and fibrinogen levels may be necessary.

Anticoagulation is contraindicated in patients with life-threatening or serious bleeding (e.g., intracranial, retroperitoneal, or pericardial). Patients with symptomatic thromboemboli, extensive fibrin deposition, and persistent coagulation abnormalities despite replacement of hemostatic factors, solid tumors, or chronic DIC may benefit from heparin therapy. Venous thromboembolism prophylaxis is recommended for critically ill, nonbleeding patients with DIC.[84]

Use of antifibrinolytics in patients with DIC is not recommended.[84] Since antifibrinolytics increase fibrin deposition, many experts believe that they are usually contraindicated. In patients with chronic liver disease who manifest dominant fibrinolysis, attempts to inhibit the fibrinolytic system have generally been unsuccessful. Although patients with acute promyelocytic leukemia have hyperfibrinolysis as the dominant clinical feature of their condition, there is no clear role for the routine use of heparin or antifibrinolytic therapy.[87]

Activated protein C modulates coagulation (Fig. 110–5). Activation of protein C may be impaired during sepsis. Drotrecogin alfa (recombinant human activated protein C) administration resulted in an absolute reduction in mortality of 6.1% from severe sepsis without undue bleeding in the Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) trial.[84] In a post hoc analysis, adults with DIC scores ≥5 have a more favorable response to drotecogin resulting in a 20% relative risk reduction in mortality over those with lower scores.[88] The pediatric trials closed prematurely due to lack of benefit. Patients must be carefully chosen to minimize bleeding complications. A recent retrospective review compared patients treated with bleeding precautions listed in the drotrecogin package insert that were not allowed in the PROWESS trial with those who did not.[89] Examples of these bleeding precautions include concurrent heparin use, platelet inhibitor use within 7 days, platelet count less than 30,000 cells/mm^3 (30 × 10^9/L), and recent surgery. This review found serious bleeding events in 35% of patients with any baseline bleeding precaution versus only 3.8% in patients without.[89]

Evaluation of Therapeutic Outcomes

The management of DIC is surrounded by controversy, and the optimal approach to these patients is still to be determined. Diagnosis and treatment of the underlying disease should be the goal in all cases. Determination of the dominant process (i.e., hemorrhage vs. thrombosis) can help focus the treatment approach but is often impossible.

Risk versus benefit, as well as any contraindications, should be considered at the start of any given therapy for each patient. Monitoring therapy for DIC with laboratory tests can be difficult because the underlying process can cause a variety of laboratory abnormalities. Trending of the DIC score over time may offer some benefit. In addition, it is important to combine laboratory parameters with clinical assessment to make rational treatment adjustments. Aggressive hemodynamic stabilization and other supportive measures to prevent organ failure are also important in the overall management and prognosis of patients with DIC.

VITAMIN K DEFICIENCY

Vitamin K is a fat-soluble vitamin. Vitamin K_1, phytonadione, is found in green vegetables. Bacteria in the large intestine produce vitamin K_2, the menaquinones, which require bile salts to be solubilized and absorbed.[90] Vitamin K_3, manadion, is a synthetic, water-soluble product associated with hemolytic anemia, indirect hyperbilirubinemia, and kernicterus when given in high doses.[90]

Vitamin K is a cofactor for activation of factors II, VII, IX, and X.[90] Vitamin K is required for γ-carboxylation of these clotting factors. Without vitamin K, these factors cannot bind calcium or bind to negatively charged phospholipid membranes and thus remain inactive precursors. Vitamin K is also necessary for the active forms of proteins C and S, which inhibit factors Va and VIIIa.[90] In most clinical situations, vitamin K deficiency causes a bleeding diathesis as a result of marked deficiency of factors II, VII, IX, and X referred to as vitamin K deficiency bleeding (VKDB). A diagnosis of VKDB is considered if the INR is ≥4 or PT ≥4 seconds above normal in the presence of a normal platelet count and fibrinogen level and the absence of a known etiology.[90] VKDB can be confirmed if coagulation tests normalize within 2 hours of parenteral vitamin K administration.[90]

Hemorrhagic Disease of the Newborn

Newborns have limited vitamin K stores at birth since transplacental passage is limited.[90] The level may continue to fall during the neonatal period because the infant's gut has not had sufficient time to undergo bacterial colonization, so the infant lacks hepatic stores. Normal menaquinone stores are not present in the liver until 2 to 3 months of age.[90] Breast milk contains a low content of vitamin K in comparison with infant formulas; therefore, breast-fed infants are more vulnerable to developing VKDB.[90] Premature infants are at increased risk for VKDB.[90]

Bleeding within 24 hours of birth, early VKDB, is almost exclusively the result of maternal ingestion of drugs that inhibit vitamin K, such as carbamazepine, phenytoin, barbiturates, warfarin, rifampin, or isoniazid. The incidence of drug-induced early VKDB without maternal vitamin K supplementation is 6% to 12%.[90] Clinical presentation is severe bleeding, usually intracranial or intraabdominal.

Classic VKDB usually appears during the first week of life and results from the lack of prophylactic vitamin K administration at birth. The incidence of classic VKDB is less than 2% without supplementation. Clinical presentation is often mild consisting of bruising, umbilical bleeding, or gastrointestinal bleeding.

Risk factors for late VKDB, which occurs at 2 to 12 weeks, include cholestatic liver disease, cystic fibrosis, α_1-antitrypsin deficiency, exclusive breast-feeding, and failure to give adequate vitamin K at birth.[90] The incidence of late VKDB is approximately 1 in 20,000 births without supplementation.[90] Clinical presentation is severe bleeding, most commonly intracranial (50%) with a mortality rate of 20%.[90] Use of oral vitamin K at birth is associated with a higher

incidence of late VKDB most likely due to a lack of compliance with the long treatment course required. It is presumed that the intramuscular route of administration allows the vitamin K to act as a depot preparation and may explain the virtual eradication of late VKDB with this route.

The levels of vitamin K–dependent coagulation factors are low at birth. Without adequate vitamin K, these levels may fall even further. In this situation, PT and aPTT are prolonged, but the thrombin time, fibrinogen level, and platelet count are normal. Most infants achieve adult levels by 6 months of age if intramuscular phytonadione was given at birth.

8 In the United States, infants usually receive 1 mg of phytonadione intramuscularly at birth for VKDB prophylaxis. Reduced doses are recommended for preterm infants: 0.3 mg for birth weight less than 1,000 g and 0.5 mg for those 1,000 to 1,500 g at birth.[90] The speed of repletion depends on the amount of milk or formula received. Controversy has arisen over whether the high plasma vitamin K levels achieved with intramuscular injection lead to an increased incidence of childhood cancer. This risk has not been substantiated, and the benefits of widespread use outweigh the minimal risk.[91] Fresh-frozen plasma is used to treat life-threatening hemorrhages.

Malabsorption

Patients may become deficient in vitamin K as a result of poor nutrition or malabsorption. A careful dietary history is important in this regard. Broad-spectrum antibiotics may sterilize the large intestine and prevent vitamin K_2 production.

Vitamin K absorption depends on both bile acids and pancreatic enzymes to create micelles.[90] Malabsorption resulting from diseases of the intestines or pancreas, such as cystic fibrosis, Crohn disease, ulcerative colitis, cholestatic liver disease, celiac disease, amyloidosis, Whipple disease, and short-bowel syndrome, may cause abnormal development in children, weight loss, muscle wasting, steatorrhea, vitamin deficiencies, and anemia. Significant malabsorption can occur even without the symptoms of diarrhea or steatorrhea. VKDB may be the first sign of malabsorption.

TREATMENT

Vitamin K Deficiency

Phytonadione is used to treat vitamin K deficiency. The dose, frequency, and duration of vitamin K administration depend on the severity of the deficiency and the patient's response. Vitamin K can be administered orally, intramuscularly, subcutaneously, or intravenously. After an oral dose of vitamin K_1, blood coagulation factors increase within 6 to 12 hours. When vitamin K_1 is administered parenterally, PT may take 12 to 24 hours to normalize, although improvement usually occurs within 1 to 2 hours. Failure of vitamin K_1 to correct PT after 48 hours should raise suspicion about the etiology of the coagulation abnormality (e.g., liver disease).

The appropriate route of administration depends on the severity and the cause of the vitamin K deficiency. For instance, in patients with severe hypoprothrombinemia, it is best to avoid the intramuscular route because of the risk of hematoma formation. Due to polyethoxylated castor oil use as an emulsifier causing rare anaphylactic reactions when phytonadione is given intravenously, this route often is restricted to patients who are thrombocytopenic or unable to absorb the drug via the gastrointestinal tract.[90] Vitamin K can be administered subcutaneously to patients without intravenous access. Patients with life-threatening bleeding should receive fresh-frozen plasma as a source of vitamin K–dependent factors to ensure immediate correction.

Patients with malabsorption, cholestasis, or obstructive jaundice may require parenteral administration of vitamin K. Phytonadione 10 mg weekly usually is sufficient in adults. Children with chronic cholestasis receiving 2.5 to 5 mg orally 2 to 7 times per week continue to have low vitamin K levels, but normal PT.[90] Doses sufficient to maintain normal PT may not be enough for osteocalcin carboxylation and may not prevent osteopenia.[90] Patients on long-term total parenteral nutrition should receive daily supplementation.

COAGULOPATHY AND LIVER DISEASE

Bleeding disorders can be associated with acute or chronic liver disease. The degree of coagulopathy correlates with the degree of hepatocellular disease. The liver synthesizes the blood coagulation factors and inhibitors of coagulation (e.g., antithrombin and proteins C and S), so patients are at risk for bleeding and clotting. All clotting factors except factor VIII and von Willebrand factor are decreased in liver failure.[6] Vitamin K–dependent clotting factors may be defective due to decreased gamma-carboxylation secondary to vitamin K deficiency.[92] The ability of the liver to clear activated clotting factors and their degradation products is reduced with liver failure. Primary fibrinolysis occurs due to decreased levels of the inhibitors of plasmin activation.[6,93]

Dysfibrinogenemia, portal hypertension, endothelial dysfunction, and renal failure may also confound the situation in patients with advanced disease.[92] Platelet count and function are decreased in patients with liver disease. Hypersplenism is the main cause of thrombocytopenia. Decreased platelet function may result from increased production of endothelial-derived platelet inhibitors. The development of DIC may worsen the coagulopathy.

PT, aPTT, and thrombin time are useful in screening for a deficiency of liver-dependent factors. PT is sensitive to deficiencies in the vitamin K–dependent factors. International Normalized Ratio should not be used in these patients unless the relevant international sensitivity index for this category of patients is used.[6] aPTT helps to determine deficiencies in factor IX and other factors. The accuracy of PT/aPTT in patients with cirrhosis is dependent on many factors, and these are often poor predictors of bleeding.[6,92] Thrombin time can help to detect hypofibrinogenemia, dysfibrinogenemia, and the presence of FDPs that interfere with fibrin polymerization. Defects in polymerization may occur before severe hypofibrinogenemia and may be an indication of the degree of liver dysfunction. Relatively stable platelet count, normal or high factor VIII, and normal D-dimer should distinguish from DIC.

Factor V is synthesized by hepatic cells but is not dependent on vitamin K. Therefore, it may be useful in distinguishing vitamin K deficiency from liver disease. Deficiency of antithrombin occurs with severe hepatocellular disease and may contribute to the development of DIC. In acute hepatic failure, the level of plasminogen may be low, reflecting decreased synthesis or increased catabolism associated with DIC.

TREATMENT

Coagulopathy and Liver Disease

The inherent problem with treating patients with liver dysfunction prophylactically or in response to coagulopathy is the inadequacy of conventional laboratory tests to measure the bleeding risk. Despite this, correction of coagulation parameters (e.g., PT and aPTT) prior to an invasive procedure is common practice.[92] Major bleeding may

occur with normal coagulation parameters secondary to esophageal varices or peptic ulcer disease. To ensure that vitamin K deficiency is not contributing to the abnormalities, adults may receive 10 mg of vitamin K for 3 days. Treatment of the coagulopathy associated with liver disease is recommended for overt bleeding.

When a patient bleeds in association with a coagulopathy, replacement therapy with platelets and fresh-frozen plasma may decrease bleeding. Fresh-frozen plasma supplies all of the missing coagulation factors, but fluid overload may exacerbate portal hypertension. If fluid overload becomes an issue, plasma exchange may be considered. If the patient has ascites, the half-life of many of these factors is decreased, and correcting the coagulopathy is difficult. PCCs can be given, but they may increase the risk of intravascular coagulation and cause DIC if not already present. In general, use of these concentrates is not recommended. Only when administration of fresh-frozen plasma does not correct the coagulopathy and the patient continues to have serious bleeding should PCCs be considered.

The use of antifibrinolytic drugs is controversial. Aminocaproic acid is effective in decreasing soft tissue and subcutaneous bleeding.[93] Aprotinin has variable effect on decreasing blood transfusions during liver transplantation surgery.[93] Antithrombin concentrates have been evaluated in fulminant liver failure with no benefit on mortality, clinical complications, or coagulation laboratory findings. Desmopressin may decrease the bleeding time in patients with liver failure, but clinical trials in cirrhosis have been disappointing.[92]

Recombinant human factor VIIa augments thrombin burst at the site of bleeding, enhances platelet action despite thrombocytopenia or renal failure, and has the advantage of not causing fluid overload. Administration of recombinant factor VIIa has been successful for liver biopsies but not effective in treating variceal bleeding.[93] Recombinant human factor VIIa improves PT and INR, but that has not resulted in a clear reduction in bleeding for these patients.[93] The greatest risk is the risk of thrombosis. The duration of effect is generally 2 to 4 hours.[92,93]

ABBREVIATIONS

aPCC: activated prothrombin complex concentrate

aPTT: activated partial thromboplastin time

BU: Bethesda unit

DIC: disseminated intravascular coagulation

FDP: fibrin degradation product

HIV: human immunodeficiency virus

NHLBI: National Heart, Lung, and Blood Institute

PAI-1: plasminogen activator inhibitor type 1

PCC: prothrombin complex concentrate

PT: prothrombin time

VKDB: vitamin K deficiency bleeding

vWF:Ag: von Willebrand factor antigen

CHAPTER 111

Sickle Cell Disease

C. Y. JENNIFER CHAN AND REGINALD MOORE

KEY CONCEPTS

1. Sickle cell disease is an inherited disorder caused by a defect in the gene for hemoglobin. Patients can have one defective gene (sickle cell trait) or two defective genes (sickle cell disease).
2. Although sickle cell disease usually occurs in persons of African ancestry, other ethnic groups can be affected. Different mutation variants can result in variation in clinical manifestations.
3. Sickle cell disease involves multiple organ systems. Usual clinical signs and symptoms include anemia, pain crisis, hepatosplenomegaly, and pulmonary diseases. Sickle cell disease can be identified by routine neonatal screening programs. Early diagnosis allows early comprehensive care.
4. Patients with sickle cell disease are at risk for infection. Prophylaxis against pneumococcal infection reduces death during childhood.
5. Hydroxyurea has been shown to decrease the incidence of painful crises, but patients treated with hydroxyurea should be carefully monitored.
6. Neurologic complications caused by vasoocclusion can lead to stroke. Chronic transfusion therapy programs have been shown to be beneficial in decreasing the occurrence of stroke in children with sickle cell disease.
7. Patients with fever greater than 38.5°C (101.3°F) should be evaluated, and appropriate antibiotics should include coverage for encapsulated organisms, especially pneumococcal organisms.
8. Pain episodes can usually be managed at home. Hospitalized patients usually require parenteral analgesics. Analgesic options include opioids, nonsteroidal antiinflammatory agents, and acetaminophen. The patient characteristics and the severity of the crisis should determine the choice of agent and regimen.
9. Patients with sickle disease should be followed regularly for healthcare maintenance issues and monitored for changes in organ functions

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Sickle cell syndromes, which can be divided into sickle cell disease (SCD) and sickle cell trait (SCT), are a group of hereditary disorders characterized by the presence of sickle cell hemoglobin (HbS) in red blood cells. SCT is the heterozygous inheritance of one normal cell and one sickle cell hemoglobin (HbAS) gene. Individuals with SCT are usually asymptomatic. SCD can be of homozygous or compounded heterozygous inheritance. Homozygous HbS (HbSS) is called sickle cell anemia (SCA); heterozygous inheritance of HbS compounded with another mutation results in sickle cell hemoglobin C (HbSC), sickle cell β-thalassemia (HbSβ^+-thal and HbSβ^0-thal), and some other rare phenotypes.[1,2]

Over the years, much progress has been made in identifying the molecular and functional defects and understanding the relationship between genotypes and clinical severity of the disease. Ongoing research involves investigation of pharmacotherapy with various effects on the pathogenesis of the disease.[1–5]

SCD is a chronic illness with significant burden for family and society.[2,6,7] Frequent crisis episodes can interrupt schooling and result in employment difficulties. Acute complications of the disease can be unpredictable, rapidly progressive, and life threatening. Later in life, chronic organ damage can develop. Because of the complexity and seriousness of the illness, it is essential that comprehensive care is available and that all providers involved have a good understanding of the disease and its management options.[1–3]

EPIDEMIOLOGY

2 SCD affects millions of people worldwide and is most common in people with African heritage. In particular, the disease is common among those with ancestors from sub-Saharan Africa, India, Saudi Arabia, and Mediterranean countries. In the United States, about 70,000 Americans have SCD occurring in 1 in 500 African American births. Approximately 2 million Americans have SCT with a prevalence rate of 1 in 12 African Americans. The most common SCD genotype is HbSS (~65%), followed by HbSC (~25%), HbSβ^+-thal (~8%), and HbSβ^0-thal (~2%). Other variants account for less than 1% of patients.[2,5,8–10]

In Africa, more than 200,000 infants are born with the disease each year. In some areas of sub-Saharan Africa, SCD occurred in up to 2% of all children. The prevalence rate of SCT in Africa varies across regions, ranging from 15 to 45% in West Africa, 1 to 2% on the North African coast, and less than 1% in South Africa. The frequencies of SCT directly determine the prevalence of SCD at birth. For example, 24% of the Nigerian population are carriers, and the prevalence of SCD is about 20 per 1,000 births, resulting in more than 100,000 infants born with SCD each year.[8–11]

The distribution of SCT reflects the survival advantage in regions (tropical areas) where malaria is endemic as the gene mutation offers partial protection against serious malarial infection.

Abnormal red blood cells (RBCs) are less easily parasitized by *Plasmodium falciparum* than normal RBCs. The incidence of the sickle cell gene in a population correlates with the historical incidence of malaria.[2,8,11]

Other areas with sickle cell mutation are the Arabian Peninsula, the Indian subcontinent, and the Mediterranean region. HbS has been reported in up to 25% in certain Middle Eastern populations and greater than 30% in Greece and Cyprus. Genetic analysis shows that the mutation found in Arabic patients is different from the mutation in those of African descent. Sickle cell gene mutation variants have been associated with different geographic locations and may be responsible for variations in clinical manifestations. In Africa, the variants are Senegal (Atlantic West Africa), Benin (Central West Africa), Bantu (Central African Republic), and Cameroon. Arab-Indian haplotype is seen in certain areas of Saudi Arabia and India. Genetic studies performed through newborn screening programs in the United States showed that Benin haplotype was the most frequent (63%), followed by the Bantu (14%), Senegal (9%), Cameroon (4%), and Saudi Arabia (2%).[2,8,11]

ETIOLOGY

Normal hemoglobin (hemoglobin A [HbA]) is composed of two α chains and two β chains ($\alpha_2 \beta_2$). The biochemical defect that leads to the development of HbS involves the substitution of valine for glutamic acid as the sixth amino acid in the β-polypeptide chain. Another type of abnormal hemoglobin, hemoglobin C (HbC), is produced by the substitution of lysine for glutamic acid as the sixth amino acid in the β-chain. Structurally, the α-chains of HbS, HbA, and HbC are identical. Therefore, it is the chemical differences in the β-chain that account for sickling and its related sequelae.[1,2,5,11]

SCA is a form of SCD in which the patient has inherited both genes that code for formation of HbS, one from each parent (HbSS). Figures 111–1, 111–2, 111–3, and 111–4 show the probability of inheritance with each pregnancy for the offspring of parents with HbA, SCT, and SCA. If both parents are carriers, the offspring will have a 25% risk of having SCD and a 50% risk of being a carrier (see Fig. 111–1). β-Thalassemia can be found in conjunction with HbS. Because patients with HbSS and HbSβ^0-thal do not have normal β-globin production, they usually have a more severe course than those with HbSC and HbSβ^+-thal. As discussed earlier, several haplotypes characterize the sickle cell gene, resulting in different clinical and hematologic courses. Included among these types are the three most commonly found in the United States: the Bantu haplotype, characterized by severe disease; the Senegal haplotype, characterized by mild disease; and the Benin haplotype, characterized by a course intermediate to that of the other two haplotypes. Although there are a number of other haplotypes seen around the world, the major types include Saudi Arabian and Cameroon. Both of these types usually follow milder courses of illness.[2,5,11]

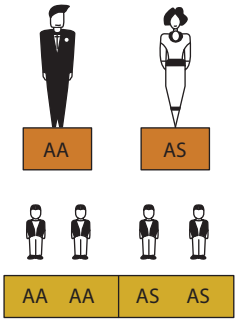

FIGURE 111-2. Sickle cell gene inheritance scheme for one parent with sickle cell trait (SCT) and one parent with no sickle cell gene. Possibilities with each pregnancy: 50% normal (AA); 50% SCT (AS). (A, normal hemoglobin; S, sickle cell hemoglobin.)

PATHOPHYSIOLOGY

Normal adult RBCs contain predominantly HbA (96%). Other forms of hemoglobin are HbA_2 (2% to 3%) and fetal hemoglobin (less than 2%). Fetal hemoglobin (HbF) is present predominantly in fetal RBCs. Instead of β chains in HbA or HbS, HbF contains two γ chains ($\alpha_2\gamma_2$). The switch from production of γ chains to β chains occurs shortly before birth. A few red cell clones remain to produce HbF postnatally. Increased production of HbF is seen under severe erythroid stress, such as anemia, hematopoietic stem cell transplantation, or chemotherapy. Both water and hemoglobin content in the RBCs determine the mean corpuscular hemoglobin concentration (MCHC). Passive diffusion and active transport regulate intracellular cation and volume contents, which determine the intracellular viscosity of RBC. Normal RBCs are biconcave shape and able to deform to squeeze through capillaries. As RBCs age, MCHC increases, deformability decreases, and the cells are removed by the mononuclear phagocytic system.[5,11,12,13]

In the pathogenesis of SCD, three known problems are primarily responsible for various clinical manifestations: impaired circulation, destruction of RBCs, and stasis of blood flow. These three problems

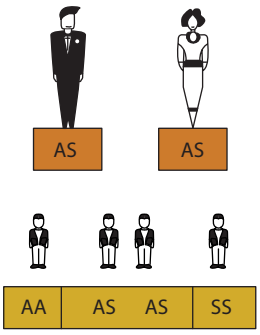

FIGURE 111-1. Sickle cell gene inheritance scheme for both parents with sickle cell trait (SCT). Possibilities with each pregnancy: 25% normal (AA); 50% SCT (AS); 25% sickle cell anemia (SS). (A, normal hemoglobin; S, sickle cell hemoglobin.)

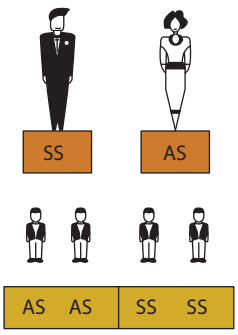

FIGURE 111-3. Sickle cell gene inheritance scheme for one parent with sickle cell trait (SCT) and one parent with sickle cell anemia (SCA). Possibilities with each pregnancy: 50% SCA (SS); 50% SCT (AS). (A, normal hemoglobin; S, sickle cell hemoglobin.)

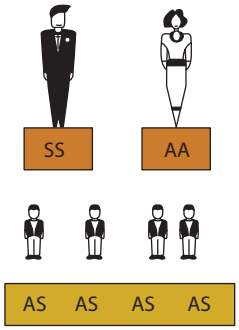

FIGURE 111-4. Sickle cell inheritance scheme for one parent without sickle cell gene and one parent with sickle cell anemia (SCA). Possibilities with each pregnancy: 100% SCT (AS). (A, normal hemoglobin; S, sickle cell hemoglobin.)

probably relate directly to two major disturbances involving RBCs: polymerization and membrane damage (Fig. 111–5).

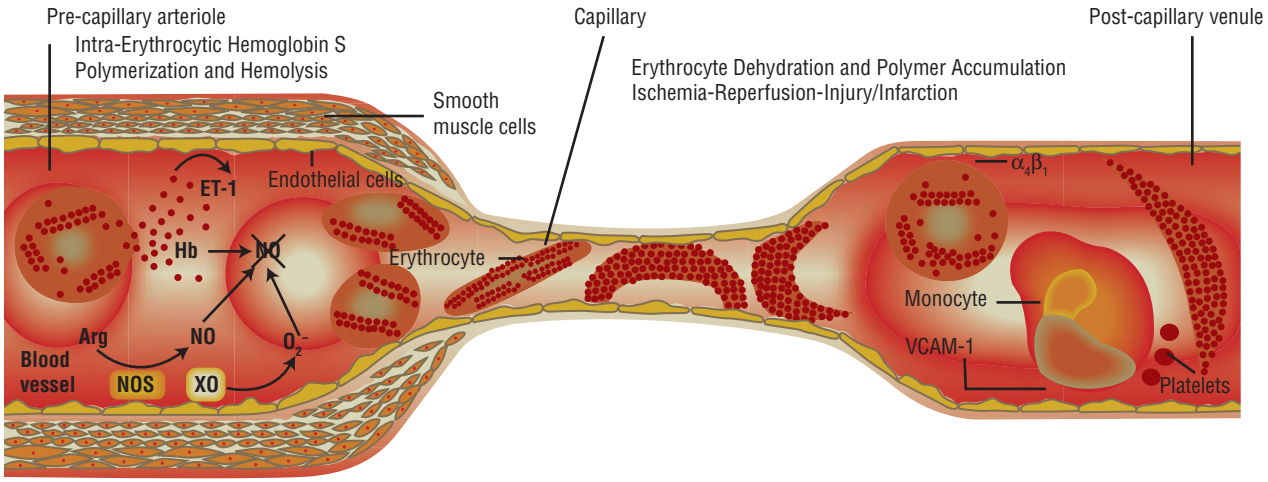
The solubilities of HbS and HbA are the same when oxygenated. Because of increased hydrophobicity as a result of valine-substituting glutamic acid, solubility of deoxygenated HbS is reduced to 17 g/dL (170 g/L; 10.55 mmol/L). Saturation of deoxy-HbS leads to intermolecular binding and formation of thin bundles of fibers, which initially are unstable, but increased binding of deoxy-HbS eventually results in cross-linking fibers and stable polymers. This process is influenced by MCHC, temperature, intracellular pH, and the amount of HbS. Polymerization allows deoxygenated hemoglobin molecules to exist as a semisolid gel that protrudes into the cell membrane, leading to distortion of RBCs (sickle shaped) and loss of deformability. The presence of sickled RBCs increases blood viscosity and encourages sludging in the capillaries and small venous vessels. Such obstructive events lead to local tissue hypoxia, which tends to accentuate the pathologic process.[12–14]

When reoxygenated, polymers within the RBCs are lost, and the RBCs eventually return to normal shape. This process contributes to the vasoocclusive manifestation in that HbS is able to squeeze into microvasculature when oxygenated, but becomes sickled when deoxygenated. This cycle of sickling and unsickling results in damage to the cell membrane, loss of membrane flexibility, and rearrangement of surface phospholipids. Membrane damage also alters ion transport, resulting in potassium and water loss, which can lead to a dehydrated state that enhances the formation of sickled forms. After continual repetitions of the process, the RBC membrane develops into a more rigid form, irreversibly sickled cell (ISC). Unlike the reversible sickle cells, which have normal morphology when oxygenated, ISCs are elongated cells and remain sickled when oxygenated. More rigid membranes of HbS-containing RBC retard their flow, particularly through the microcirculation. In addition, sickled RBCs tend to adhere to vascular endothelial cells, which further increase polymerization and obstruction.

Intermolecular binding and polymer formation are reduced by HbF and to a lesser degree by HbA_2. RBCs that contain HbF sickle less readily than cells without. ISCs, not surprisingly, have a low HbF level. Increased levels of HbF, as in the case of the Saudi Arabian genotype, result in more benign forms of SCD. The amount of HbF and HbA_2 in relation to HbS influences clinical manifestations and accounts for the variability in severity among different SCD genotypes.

Intravascular destruction of sickle cells can occur at an accelerated rate. The stresses of circulation, and repetitive sickle–unsickle cycles are likely to lead to cell fragmentation. Damage to the cell membrane promotes cell recognition by macrophages. Rigid ISCs are easily trapped, resulting in short circulatory survival and chronic hemolysis. The typical sickled cell survives for about 10 to 20 days, whereas the life span of a normal RBC is 100 to 120 days.

In addition to sickling, other factors are also responsible for the clinical manifestations associated with SCD. Obstruction of blood flow to the spleen by sickle cells can result in functional asplenia, defined as the loss of splenic function with an intact spleen. These patients can also have deficient opsonization. Impaired splenic function increases susceptibility to infection by encapsulated organisms, particularly pneumococcal disease. Coagulation abnormalities in SCD can be the result of continuous activation of the hemostatic system or disorganization of the membrane layer.[1,11–14]



Vascular instability due to:
- Inactivation of NO and induction of endothelin-1 by cell-free hemoglobin
- Inactivation of NO by superoxide generated by xanthine oxidase

Pre-capillary vascular obstruction due to rigid erythrocytes

Inflammation-induced adhesion of sickle erythrocytes, leukocytes platelet-monocyte aggregates mediated through VCAM-1 and other adhesion molecules

FIGURE 111-5. Pathophysiology of sickle cell disease. Sickle cell disease. In: Hall JB, Schmidt GA, Wood LDH. Principles of Critical Care, 3rd ed. New York: McGraw-Hill, 2005:1658.)*

CLINICAL PRESENTATION

3 SCD is usually identified by routine neonatal screening programs. The sensitivity and specificity of screening methods (isoelectric focusing, high-performance liquid chromatography, or electrophoresis) are 93.1 to 100% and 99.9 to 100%, respectively. For infants with a positive screening result, a second test should be performed by 2 months of age to confirm the diagnosis. More than 98% newborns in the United States are screened for SCD to identify the disease. Even with universal screening, infants with SCD are sometimes not identified at birth because of extreme prematurity, prior blood transfusion, inability to contact family, or clerical errors.[2,5,9]

SCD involves multiple organ systems, and its clinical manifestations vary greatly between and among genotypes (Table 111–1). Persons with SCT are usually asymptomatic and are not considered to have clinical disease. However, some clinical signs and symptoms can occur, and patients should be cautious when participating in exercise under extreme conditions, such as high altitude or military training. Sickling of RBCs in the renal medulla can result in loss of ability to maximally concentrate urine. Patients with such impairment can be at risk of dehydration during periods in which the body normally conserves water. Microscopic hematuria has been observed, and gross hematuria can occur after heavy exercise. An increased incidence of urinary tract infection in women, especially during pregnancy, has been reported.[9,11,15]

The feature presentations of SCD are hemolytic anemia and vasoocclusion. In patients who are homozygous for HbS, anemia usually appears from 4 to 6 months after birth. The delay in presentation is because, during those months, HbF in the infant's RBC is gradually replaced by HbS, which typically leads to attacks of pain frequently accompanied by fever. Pneumonia and splenomegaly are also common findings. Infants can also present with pain and swelling of the hands and feet, commonly referred to as *hand-and-foot syndrome* or *dactylitis*.[1,2,5,7,9]

The usual clinical signs and symptoms associated with SCA include chronic anemia; fever and pallor; arthralgia; scleral icterus; abdominal pain; weakness; anorexia; fatigue; enlargement of the liver, spleen, and heart; and hematuria. Laboratory findings include low hemoglobin level around 8 g/dL (80 g/L; 4.97 mmol/L) and increased reticulocyte, platelet, and white blood cell (WBC) counts. The peripheral blood smear demonstrates sickle cell forms.[1,2,5,8,9]

Presentation of patients with HbSC disease is less severe than that of SCA and is characterized primarily by mild anemia (hemoglobin levels above 9 g/dL [90 g/L; 5.59 mmol/L]), infrequent episodes of pain, persistence of splenomegaly into adult life, and excessive target cells in the peripheral blood smear. In patients with heterozygous HbS and β-thalassemia gene, severity of disease depends on the thalassemia gene involved.[1,2,5,9,11]

Patients with SCD experience delayed growth and sexual maturation. Both height and weight are usually below average, and the poor growth cannot be explained by nutritional factors alone. Fertility problems tend to occur more often, and some menstrual abnormalities are more common in female SCD patients than in normal women. Other typical physical characteristics include a protuberant abdomen with exaggerated lumbar lordosis, usually an asthenic appearance with rather long extremities and tapered fingers, and frequently a barrel-shaped chest.[1,2,5,9,11,16]

The previously high mortality rate of early childhood has been reduced for patients with SCD with availability of public health programs and comprehensive care.[1,9,17] The median survival rate is estimated to be 42 years for males and 48 years for females for HbA, and 60 years for males and 68 years for females for HbSC.[9] Predictors for severe disease in children who are less than 10 years of age include dactylitis before 1 year of age, an average hemoglobin level less than 7 g/dL (70 g/L; 4.34 mmol/L) in the second year of life, and WBC count greater than 13,700 cells/mm^3 (13.7×10^9/L) in the absence of infection. Early acute chest syndrome during the first 3 years of life is a predictor for recurrent episodes throughout childhood. Children with concomitant SCD and asthma have increased episodes of acute chest syndrome and stroke and increased mortality. Risk factors for early death in adults with SCD include acute complications such as pain crisis, anemic events, acute chest syndrome, renal failure, and pulmonary disease.[3,5,17–22] Today, with longer survival for SCD, chronic manifestations of the disease contribute to the morbidity later in life.

TABLE 111-1 Clinical Features of Sickle Cell Trait and Common Types of Sickle Cell Disease

Type	Clinical Features
Sickle cell trait (SCT)	Rare painless hematuria; normal Hb level; heavy exercise under extreme conditions can provoke gross hematuria and complications
Sickle cell anemia (SCA)	Pain crises, microvascular disruption of organs (spleen, liver, bone marrow, kidney, brain, and lung), gallstone, priapism, leg ulcers; anemia (Hb 7–10 g/dL [70–100 g/L; 4.34–6.21 mmol/L])
Sickle cell hemoglobin C	Painless hematuria and rare aseptic necrosis of bone; vasoocclusive crises are less common and occur later in life; other complications are ocular disease and pregnancy-related problems; mild anemia (Hb 10–12 g/dL [100–120 g/L; 6.21–7.45 mmol/L])
Sickle cell β^+-thalassemia	Rare crises; milder severity than sickle cell disease because production of HbA; Hb 10–14 g/dL (100–140 g/L; 6.21 –8.69 mmol/L) with microcytosis
Sickle cell β^0-thalassemia	No HbA production; severity similar to SCA; Hb 7–10 g/dL (70–100 g/L; 4.34–6.21 mmol/L) with microcytosis

HbA, hemoglobin A; Hb, hemoglobin.

COMPLICATIONS

ACUTE COMPLICATIONS

Fever and Infection

Functional asplenia and failure to make antibodies against encapsulated organisms contribute to the high risk of overwhelming sepsis in patients with SCD. The most common pathogen is *Streptococcus pneumoniae*. Other encapsulated organisms are *Haemophilus influenzae* and *Salmonella*, and the latter has been known to cause osteomyelitis and pneumonia in SCD. *Mycoplasma pneumoniae* should be considered in older children with infiltrates on chest radiograph. Viral infections (e.g., influenza and parvovirus B19) can result in severe morbidity.[1,5,23,24]

All SCD patients with fever greater than 38.5°C (101.3°F) must be evaluated to determine the extent of sepsis; workup can include physical examination, complete blood count with reticulocyte count, blood culture, chest radiograph, urinalysis, and urine culture. Lumbar puncture may be needed, especially in young children and toxic-appearing children. A low threshold for empiric therapy compared to that in the general population is recommended.[1,5,9,11,24]

Neurologic

Neurologic abnormalities can occur in both adults and children. Vasoocclusive processes occasionally lead to cerebrovascular

occlusion that manifests itself as the signs and symptoms of stroke, such as drowsiness, paralysis, transitory or permanent blindness, aphasia, visual disturbances, spinal cord infarction, and convulsions. Behavioral and performance changes can occur in patients with asymptomatic infarction. The risk of cerebral infarct in HbSS is 11% by age 20 years and 24% by age 45 years with a recurrence rate as high as 70% in 3 years. Some patients recover rapidly and completely, although others are left with permanent neurologic deficits. Evaluation of acute events include computed tomography (CT) scan and magnetic resonance imaging (MRI), magnetic resonance angiography (MRA) for asymptomatic infarction, and transcranial Doppler (TCD) ultrasound to detect abnormal velocity and identify high-risk patients. In addition, electroencephalography (EEG) can be used if there is a history of seizure. Some patients who have SCA with no prior history of stroke have been found to have changes on MRI of the brain consistent with infarction or ischemia. These "silent infarcts" have been reported to occur in up to 22% of HbSS patients and can be associated with increased risk of stroke and decreased neurocognitive functions.[1,5,25–28]

Acute Chest Syndrome

Acute chest syndrome is the leading cause of death among patients with SCD. It is characterized by a new pulmonary infiltrate associated with one or more other symptoms (such as cough, dyspnea, tachypnea, chest pain, fever, wheezing, and new-onset hypoxia), and an equivocal response to antibiotic therapy. As many as one-half of patients with SCD experience at least one episode of acute chest syndrome. Pulmonary infarcts often involve the lower lobes of the lungs and are a frequent cause of pleural effusions. Pneumonia occurs most often in the middle and upper lobes. These pulmonary manifestations must be recognized early and managed aggressively because the patient can rapidly progress to pulmonary failure and death.[29–32]

Priapism

Sickling in the sinusoids of the penis can cause priapism, a sustained painful erection that can last several hours or days; 30 to 45% of patients with SCD will present at least one episode of priapism during their lifetime. Impotence has been reported after repeated episodes. Recurrent and severe priapism is a predictor for other end-organ damage. ASPEN (*a*ssociation of *s*ickle cell disease, *p*riapism, *e*xchange transfusion, and *n*eurologic events) syndrome has occurred in some patients with priapism 1 to 11 days after partial exchange transfusion. This syndrome can range from headaches and seizures to obtundation requiring ventilation.[1,9,11,33]

Sickle Cell Crisis

Chronic hemolytic anemia in the SCD patient is periodically interrupted by crises, particularly in childhood (see Table 111–2). Patients with HbSS disease experience crises more often than do patients with HbSC disease or some other variants. Although fever, infections, dehydration, hypoxia, acidosis, and sudden temperature alterations can precipitate crises, multiple factors often contribute to development of a crisis.

Vasoocclusive Pain Crisis The most common type of crisis is the vasoocclusive crisis, which is usually characterized by pain affecting the involved areas, without changes in hemoglobin. Laboratory changes that can be seen include leukocytosis, increased fibrinogen levels, and decreased serum pH and bicarbonate level. Dactylitis (hand-and-foot syndrome) occurs in infancy and early childhood and is characterized by redness and swelling of the dorsal aspects of the hands, feet, fingers, and toes. The episodes are painful but usually do not result in permanent damage.[1,5,8,9,11,34]

TABLE 111-2 Sickle Cell Crisis

Vasoocclusive pain crisis[a]
Clinical features: Acute painful infarction without changes in Hb; almost all patients with SCA will have episodes of acute pain. Recurrent acute crises result in bone, joint, and organ damage and chronic pain. Vasoocclusive crisis most commonly involves the bones, liver, spleen, brain, lungs, and penis. Acute long bone pains can be accompanied by signs of inflammation, making it difficult to differentiate from osteomyelitis. Abdominal involvement can resemble a surgical abdomen. Precipitating factors include infection, extreme weather conditions, dehydration, and stresses.
Signs and symptoms: Deep throbbing pain; local tenderness, erythema, and swelling can be seen. Fever and leukocytosis are common. Dactylitis usually occurs in young infants. Jaundice and increased transaminases present if liver is involved.
Evaluation: Frequent physical examination, CBC, reticulocyte count, and urinalysis; based on symptomatology. The following can be needed: needle aspiration to rule out osteomyelitis, abdominal studies (radiograph, computed tomography scan, etc.), liver function tests, bilirubin, culture, and chest radiograph.
Aplastic crisis[b]
Clinical features: Acute decrease in Hb with decreased reticulocyte count (usually less than 1%); transient suppression of RBC production in response to bacterial or viral infection, most common being parvovirus B19
Signs and symptoms: Headache, fatigue, dyspnea, pallor, and tachycardia; can also present with fever, upper respiratory or gastrointestinal infection symptoms
Evaluation: CBC, reticulocyte count, radiograph, cultures (blood, urine, and throat), evaluation of viral infection (e.g., parvovirus titers)
Acute splenic sequestration crisis[c]
Clinical features: Acute exacerbation of anemia due to sequestration of large blood volume by the spleen. More commonly seen in patients with functioning spleens (e.g., infants and adults with HbSC disease); onset often is associated with viral or bacterial infections; recurrences are common and can be fatal.
Signs and symptoms: Sudden onset of fatigue, dyspnea, and distended abdomen; rapid decrease in Hb and Hct with elevated reticulocyte count, abdominal pain, splenomegaly, vomiting, hypotension, and shock
Evaluation: Close monitoring of vital signs, spleen size, and oxygen saturation, CBC, reticulocyte count, and cultures

CBC, complete blood count; HbSC, sickle cell hemoglobin C; Hb, hemoglobin; Hct, hematocrit; RBC, red blood cell; SCA, sickle cell anemia.

[c]From Montalembert,[1] Driscoll,[5] National Institutes of Health,[9] and Stuart and Nagel.[11]

Aplastic Crisis Aplastic crisis is characterized by a decrease in the reticulocyte count and a rapidly developing severe anemia. The bone marrow is hypoplastic. There can be associated pain. The crisis is typically caused by a viral infection, particularly parvovirus B19.[2,5,9,23,24]

Splenic Sequestration Crisis This is a sudden massive enlargement of the spleen resulting from the sequestration of blood from the mononuclear phagocytic system. Hematocrit and hemoglobin concentrations dramatically fall, with reticulocytosis and no evidence of marrow failure or accelerated hemolysis. The trapping of the sickled RBCs by the spleen also leads to a decrease in circulating blood volume, which can result in hypotension and shock. The condition is most often seen in infants and children because their spleens are intact, and can cause sudden death in young children. Repeated infarctions lead to autosplenectomy as the disease progresses; the incidence therefore declines as adolescence approaches.[1,5,9,11]

CHRONIC COMPLICATIONS

SCD manifests in a variety of chronic problems involving multiple organs. Pulmonary hypertension has been reported to be a

risk factor for death in adult patients with SCD.[19,35] Pulmonary hypertension is frequently reported in children and adolescents, although its significance has not been established.[36,37] Headache and weakness of one leg or arm is a symptom associated with acute neurologic events, and pseudotumor cerebri presenting with severe headache and blurred vision has also been reported.[25,38]

Bone diseases are common in SCD. Osteonecrosis, particularly of the femoral or humeral heads, causes permanent damage and disability.[39,40] Osteopenia associated with low bone formation has been reported in both boys and girls.[41] Patients with SCD also have an increased incidence of osteomyelitis; the organism most often responsible is *Salmonella*.[5,9,24] In addition to necrosis of joints, chronic leg ulcers can become a difficult skeletal problem. Ulcers are often seen after trauma or infection and are usually slow to heal.[5,9]

Ocular problems seen in patients with SCD include transient monocular blindness, visual field defects from retinal hemorrhage, retinal detachment, vitreous hemorrhage, venous microaneurysms, and neovascularization. The incidence of proliferative retinopathy in SCD patients varies from 5% to 10%. Vasoocclusion in the eye can occur as early as 20 months of age, and clinically detectable retinal diseases usually occur during adolescence and early adulthood. Despite the less systemic manifestations, patients with HbSC develop serious retinal complications more often and earlier. Annual examination with retinal evaluation is recommended for patients with SCD to prevent blindness from retinopathy and other complications.[9,42]

Cholelithiasis is a common occurrence in the SCD patient. It is the result of the chronic hemolysis that results in increased bilirubin production, leading to biliary sludge and/or stone formation. The risk of gallstones increases with age, with 14% younger than age 10 years and 50% by age 22 years. Cholecystitis, exemplified by pain in the right iliac fossa, can be confused with abdominal pain crisis.[5,9,43]

As with any anemia, cardiovascular abnormalities, including cardiac enlargement and various murmurs, can occur in patients with SCD. Patients complain of various degrees of exertional dyspnea, tachycardia, and palpitation because of the decreased oxygen-carrying capacity of the blood. Left ventricular diastolic dysfunction has been reported in 18% of adult patients and is associated with increased mortality, especially in patients with pulmonary hypertension. In children, left ventricular stiffness and left ventricular hypertrophy have been reported, and the progression is speculated to lead to diastolic dysfunction later in life. Acute myocardial infarction in young adults with SCD may not be recognized.[9,44–46]

Renal complications include hematuria, tubular acidosis, proteinuria, and hyposthenuria (inability to concentrate urine maximally). Enuresis, as a result of increased urine production, is a common complaint. Nephrotic syndrome and end-stage renal disease have also been reported in 5% to 10% of patients.[5,9]

Depression and anxiety are more common in children and adults with SCD than in the general population and have a significant impact on quality of life.[47–49] Reduced cognitive function has been reported, even in children with no evidence of cerebral infarction.[2] Delays in growth and sexual development are seen in patients with SCD.[49] Adults with SCD have decreased fertility. Finally, pregnancy introduces an increased risk for the mother with SCD and for the fetus. Some patients can experience increased frequency of pain crisis during pregnancy. The anemia of SCD can lead to intrauterine growth retardation. Preterm labor and premature delivery are common occurrences in mothers with SCD, and the risk of spontaneous abortion is increased. The incidences of cesarean delivery and pregnancy-related complications are higher when compared with mothers who do not have SCD.[9,11,50]

TREATMENT

Sickle Cell Disease

Patients with SCD require lifelong multidisciplinary care. All patients with SCD should receive regularly scheduled comprehensive medical evaluations. The goal of comprehensive care is to reduce hospitalizations, complications, and mortality. Because of the complexity of the disease, a multidisciplinary team is needed to provide medical care, education, counseling, and psychosocial support. Appropriate comprehensive care can have a positive impact on both longevity and general quality of life. This care includes the use of traditional prophylactic and general symptomatic supportive care and the use of newer, more specific therapies aimed at altering hematologic capacity and function.[1,2,5,9,11]

Treatment for patients with SCD involves the use of general measures to meet the unique demands for increased erythropoiesis. Additional interventions can be aimed at preventing or treating complications of the disease. When a crisis occurs, the type and severity of the crisis determine the appropriate therapeutic plan.

HEALTH MAINTENANCE

Immunizations

Administration of routine immunizations as recommended by the American Academy of Pediatrics is crucial. In addition to the routine immunizations, SCD patients 6 months and older should receive influenza vaccine annually. Meningococcal vaccine is also recommended for patients older than 2 years of age who are undergoing splenectomy or are functionally asplenic.[9,24,51]

Patients with SCD have impaired splenic function, which increases their susceptibility to infection by encapsulated organisms, particularly pneumococci. Prior to the routine use of penicillin prophylaxis and the development of pneumococcal vaccines, invasive pneumococcal disease was 20- to 100-fold more common in children with SCD than in healthy children. Reduced mortality rate has been associated with the introduction of the pneumococcal vaccines.[17,24,52,53]

Two different pneumococcal vaccines are available. The 13-valent pneumococcal conjugate vaccine (PCV13; Prevnar) induces good antibody responses in infants. Immunization with the PCV13 is recommended for all children younger than 24 months of age. Infants should receive the first dose after 6 weeks of age. Two additional doses should be given at 2-month intervals, followed by a fourth dose at age 12 to 15 months. The 23-valent pneumococcal polysaccharide vaccine (PPV 23; Pneumovax 23) is not recommended for use in children younger than 2 years of age because of poor antibody response. To cover for different serotypes, PPV 23 should be given at 2 years of age, administered about 2 months after the last dose of the PCV7/PCV13 and a booster dose at age 5. The recommended immunization schedule and catch-up schedule for PCV13 and PPV 23 are presented in Table 111–3.[5,9,24,54]

In addition to pneumococcal disease, the risk of meningococcal disease can be higher in SCD. Revaccination with meningococcal conjugate vaccine (MCV4) is recommended for persons with anatomic or functional asplenia due to prolonged increased risk for meningococcal disease. Those patients should be revaccinated 5 years after the previous vaccine if given at age 7 or older or 3 years after the previous vaccine if given between ages 2 and 6.[51]

TABLE 111-3 Pneumococcal Immunization for Children with Sickle Cell Disease

	Recommended Schedule
Previously unvaccinated	
Age 2–6 months	**PCV13 (Prevnar):** 3 doses 6–8 wk apart; then 1 dose at 12–15 months
Age 7–11 months	**PCV13 (Prevnar):** 2 doses 6–8 wk apart; then 1 dose at 12–15 months
Age ≥12–23 months	**PCV13 (Prevnar):** 2 doses 6–8 wk apart
Age 24–59 months	**PCV13 (Prevnar):** 2 doses 6–8 wk apart **PPV 23 (Pneumovax):** 2 doses; first dose at least 6–8 wk after last PCV7/PCV13 dose; second dose 3–5 years after the first PPV 23 dose
Age 5 years or older	**PCV13 (Prevnar):** 1 dose **PPV 23 (Pneumovax):** 2 doses; first dose at least 6–8 wk after last PCV7/PCV13 dose; second dose 3–5 years (for those age 10 years or younger) or more than 5 years (for those age older than 10 years) after the first PPV 23 dose
Previously vaccinated	
Age 12–23 months, incomplete PCV7/PCV13 series	**PCV13 (Prevnar):** 2 doses 6–8 wk apart
Age 24–59 months, received four doses of PCV7/PCV13	**PPV 23 (Pneumovax):** 2 doses; first dose at least 6–8 wk after last PCV7 dose; second dose 3–5 years after the first PPV 23 dose
Age 24–59 months, three doses PCV7/PCV13 given before 24 months of age	**PCV13 (Prevnar):** 1 dose **PPV 23 (Pneumovax):** 2 doses; first dose at least 6–8 wk after last PCV7/PCV13 dose; second dose 3–5 y after the first PPV 23 dose
Age 24–59 months, 1 dose PPV 23 given	**PCV13 (Prevnar):** 2 doses 6–8 wk apart; first dose at least 8 wk after PPV 23 dose **PPV 23 (Pneumovax):** second dose 3–5 years after first PPV 23
Age 5 years or older, received PPV 23	**PCV13 (Prevnar):** 1 dose 6–8 wk after PPV 23 **If only received 1 dose of PPV 23 (Pneumovax):** Second dose 6–8 wk after PCV7/PCV13 *and* 3–5 years (for those age 10 years or less) or more than 5 years (for those age older than 10 years) after the first PPV 23 dose

PCV7, 7-valent pneumococcal conjugated vaccine; PCV13, 13-valent pneumococcal conjugated vaccine; PPV 23, 23-valent pneumococcal polysaccharide vaccine.
From MMWR.[54]

Penicillin

4 Penicillin prophylaxis until at least 5 years of age is recommended in children with SCD, even if they have been immunized with PCV7 as prophylaxis against pneumococcal infections. Prophylactic treatment should begin at 2 months of age or earlier. An effective regimen that reduces the risk of pneumococcal infections by 84% is penicillin V potassium at a dosage of 125 mg orally twice daily until the age of 3 years, followed by 250 mg twice daily until the age of 5 years. An alternate regimen is benzathine penicillin, 600,000 units given intramuscularly every 4 weeks for children age 6 months to 6 years, and 1.2 million units every 4 weeks for those over 6 years of age for whom continued therapy is warranted. Patients who are allergic to penicillin can be given erythromycin 20 mg/kg per day twice daily. Penicillin prophylaxis is not routinely given in older children, based on a study demonstrating no benefit over placebo beyond the age of 5 years. However, continuation of oral pneumococcal prophylaxis should be evaluated on a case-by-case basis, especially in patients with a history of invasive pneumococcal infection or surgical splenectomy.[5,9,24,54]

CURRENT CONTROVERSY

The need for routine penicillin prophylaxis is controversial in HbSβ^+-thal patients because these patients have less severe disease.

Folic Acid

Patients with SCD have an increased demand for folic acid because of accelerated erythropoiesis. Conversion of homocysteine (Hcy) to methionine depends on folate, and vitamins B_6 and B_{12}. Plasma homocysteine level has been used as a marker for folate and vitamins B_6 and B_{12} status, and increased homocysteine levels have been associated with endothelial damage in pediatric SCD patients. In general, folic acid supplementation at a dose of 1 mg/day is recommended in adult patients, women who are contemplating pregnancy, and patients of all ages with chronic hemolysis.[5,9]

CURRENT CONTROVERSY

Daily supplementation with folic acid, vitamin B_{12}, and vitamin B_6 has been suggested for SCD patients to reduce risk of endothelial damage.

FETAL HEMOGLOBIN INDUCERS

HbF reduces polymer formation of HbS due to its high oxygen affinity. Increases in HbF levels significantly correlate with decreased RBC sickling and RBC adhesion. Epidemiologic studies show a relationship between HbF concentration and severity of the disease. Patients with low HbF levels have more frequent crises and higher mortality. It has been suggested that HbF level of 20% is the threshold for reduction of acute symptoms. Based on these observations, HbF induction has become a treatment modality for patients with SCD.[4,14,55]

Hydroxyurea

Hydroxyurea, a chemotherapeutic agent, increases HbF levels by stimulating the production of HbF. It also increases in the number of HbF-containing reticulocytes and intracellular HbF. Its antineoplastic activity is related to inhibition of DNA synthesis by blocking the conversion of ribonucleoside to deoxyribonucleotides. The exact mechanism of HbF production is unknown, but its cytotoxic effect in the bone marrow triggers rapid erythroid regeneration and increases erythrocyte precursors becoming HbF. In addition, hydroxyurea increases nitric oxide (NO) levels, reduces neutrophils and monocytes, has antioxidant properties, alters RBC membrane properties, increases RBC deformability by increasing intracellular water content, and decreases RBC adhesion to endothelium.[4,9,55–57]

Hydroxyurea can prevent painful crises and is FDA approved for adult patients based on a double-blind, placebo-controlled study called the Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH). In that study of 299 adults with moderate-to-severe SCD, hydroxyurea significantly reduced the frequency of painful episodes, incidence of acute chest syndrome, need for blood transfusions, and number of hospitalizations.[56] The average number of crises was 44% lower in those who received hydroxyurea, declining from 4.5 to 2.5 crises per year. The incidence of severe crises, defined as those requiring hospitalization, was also lower, with a median rate of 2.4 severe crises per year in the placebo group versus one

severe crisis per year in the hydroxyurea group. The risk of acute chest syndrome was also significantly reduced in patients receiving hydroxyurea. Of the 152 patients in the hydroxyurea group, 25 (16%) developed acute chest syndrome, as compared with 51 (35%) of the 147 patients in the placebo group. Blood transfusion requirements were decreased by 34% in the hydroxyurea group. The study was terminated early after interim analyses revealed the significant benefits. The incidence of death, stroke, and hepatic sequestration in the hydroxyurea and placebo groups was not significantly different during the 29-month evaluation period. However, the follow-up study showed a 40% reduction in mortality with hydroxyurea over a 9-year period.[56]

Although hydroxyurea is not FDA approved for children and adolescents with SCD, its use in this patient population is supported by the National Institutes of Health (NIH).[9,57] Studies in pediatric patients (Pediatric Hydroxyurea in Sickle Cell Anemia) showed similar benefits as in adults with no adverse effects on growth and development. In addition, patients treated with hydroxyurea therapy had possible recovery or preservation of splenic and brain functions, including cognitive performances. When given with a transfusion program, hydroxyurea can play an important role in preventing recurrent strokes and reducing iron overload from transfusion.[56–63] Two NIH studies are under way in children with SCD. The Pediatric Hydroxyurea Phase III Clinical Trial (BABY HUG) evaluates whether hydroxyurea therapy prevents chronic end-organ damage in young children ages 9 to 17 months. The SCA and Stroke with Transfusions Changing to Hydroxyurea (SWiTCH) trial compares hydroxyurea and phlebotomy to standard therapy for prevention of secondary stroke and management of iron overload.[62,64]

The most common side effect of hydroxyurea is bone marrow suppression, including neutropenia, thrombocytopenia, anemia, and/or decreased reticulocyte count. These hematologic side effects usually recover within 2 weeks with discontinuation of therapy. Other side effects include dry skin and hyperpigmentation of skin or nails.[56] Long-term side effects of hydroxyurea therapy in patients with SCD are not fully known. Studies in children have not demonstrated delays in growth or puberty. Myelodysplasia, acute leukemia, and chronic opportunistic infection associated with T-lymphocyte abnormalities have been reported. Longer follow-up is needed to determine its carcinogenic or leukemogenic effects. Reproductive toxicity is another concern. High-dose hydroxyurea has been shown to be teratogenic in animals, but normal pregnancies have been reported in women who received hydroxyurea during pregnancy.[5,9,55–58–61]

Clinical indications for hydroxyurea use include frequent painful episodes, severe symptomatic anemia, a history of acute chest syndrome, or other severe vasoocclusive complications. The starting dose for hydroxyurea is 10 to 15 mg/kg per day as a single daily dose (Fig. 111–6). The dosage can be increased after 8 to 12 weeks if the patient can tolerate the adverse effects and blood counts are stable. Hydroxyurea dosage should be individualized based on response and toxicity. In general, 3 to 6 months of daily administration are required before improvement is observed. Medication adherence can be an issue. Since the mean corpuscular volume (MCV) generally increases as the level of HbF increases, monitoring the MCV is an inexpensive and convenient method of monitoring response. With close monitoring, hydroxyurea can be increased by 5 mg/kg per day up to 35 mg/kg per day.[9,56]

5 Patients receiving hydroxyurea should be closely monitored for toxicity. Blood counts should be checked every 2 weeks during dose titration and every 4 to 6 weeks thereafter. Treatment should be interrupted if hematologic indices fall below the following values: absolute neutrophil count, 2,000 cells/mm^3 (2×10^9/L); platelet count, 80,000 cells/mm^3 (80×10^9/L); hemoglobin, 5 g/dL (50 g/L; 3.1 mmol/L); or reticulocytes, 80,000 cells/mm^3 if the hemoglobin concentration is less than 9 g/dL (90 g/L; 5.59 mmol/L). Other laboratory abnormalities warranting temporary discontinuation of therapy are a 50% increase in serum creatinine and a 100% increase in transaminase. After recovery has occurred, treatment should be resumed at a dose that is 2.5 to 5 mg/kg per day lower than the dose associated with toxicity. If no toxicity occurs after 12 weeks with the lower dose, the dose can be increased by 2.5 to 5 mg/kg per day. A given dose that twice produces a toxic hematologic response should not be tried again. Failure to see an increase in the MCV with hydroxyurea therapy can indicate that the marrow is unable to respond, the hydroxyurea dose is inadequate, or the patient is nonadherent.[5,9,56]

Butyrate

Butyrate, a naturally occurring fatty acid, increases HbF by altering gene expression, which leads to increased γ-globin chain production. Unlike hydroxyurea, butyrate does not appear to be cytotoxic.

Butyrate has been studied in a small number of adult patients. Initial trials with continuous-infusion butyrate showed an increase not only in HbF but also in total hemoglobin and in the number of cells containing HbF. However, a sustained effect or an associated clinical benefit has not been observed. A later study with arginine butyrate in a pulse regimen reported a sustained increase in HbF and reduction of hospitalized days in a small number of adult patients. In that study, adult patients received a 4-day course of arginine butyrate, followed by a 10- to 24-day drug-free period before the administration of the next dose. Arginine butyrate was given at a daily dose of 250 to 500 mg/kg over 6 to 12 hours. Although the results are encouraging, the need for intravenous administration can limit widespread use of the regimen.[4,9,55]

HbF production by butyrate appears to depend on pretreatment HbF. Young children may be better candidates for this therapy because they have a higher level of HbF. Oral sodium phenylbutyrate has been used for years in young children with urea cycle disorders. At high doses, side effects include transient fluid retention, rashes, and unusual body odor. Increased HbF levels were seen in patients with SCA who received both high-dose (15 to 20 g/day) and low-dose (1 to 11 g/day) regimens. In the study of low-dose sodium phenylbutyrate, increased HbF was seen within 5 weeks but may not be sustained.[4,9,55] Butyrate has been shown to heal intractable leg ulcers, and the use of arginine butyrate in patients with SCD and refractory leg ulcers is being evaluated.[65]

5-Aza-2′-Deoxycytidine (Decitabine)

5-Azacytidine and 5-aza-2′-deoxycytidine (decitabine) induce HbF by inhibiting DNA methylation, thus preventing the switch from γ- to β-globin production. Compared with 5-azacytidine, decitabine has a more favorable safety profile and is a more potent DNA methylation inhibitor. Virtually abandoned in the past because of concerns regarding the cytotoxicity of 5-azacytidine, decitabine has been studied in a small number of patients with SCD who did not respond to hydroxyurea. In one study, an increase in HbF was seen in adult patients who were resistant or intolerant to hydroxyurea with 5-aza-2′-deoxycytidine was given at a dose of 0.2 mg/kg one to three times a week subcutaneously. Reduction of vasoocclusive crisis and improved performance status were reported in four adult patients with severe SCD. The only significant toxicities observed were neutropenia and increased platelet count. Long-term clinical effects and side effects of this agent have not been fully evaluated. This agent may have a role in treating patients who fail to respond to hydroxyurea.[4,9,55,66]

Combinations of Hemoglobin F Inducers

Erythropoietin therapy has been used in some patients with SCD, and the clinical results have been inconsistent; therefore its routine

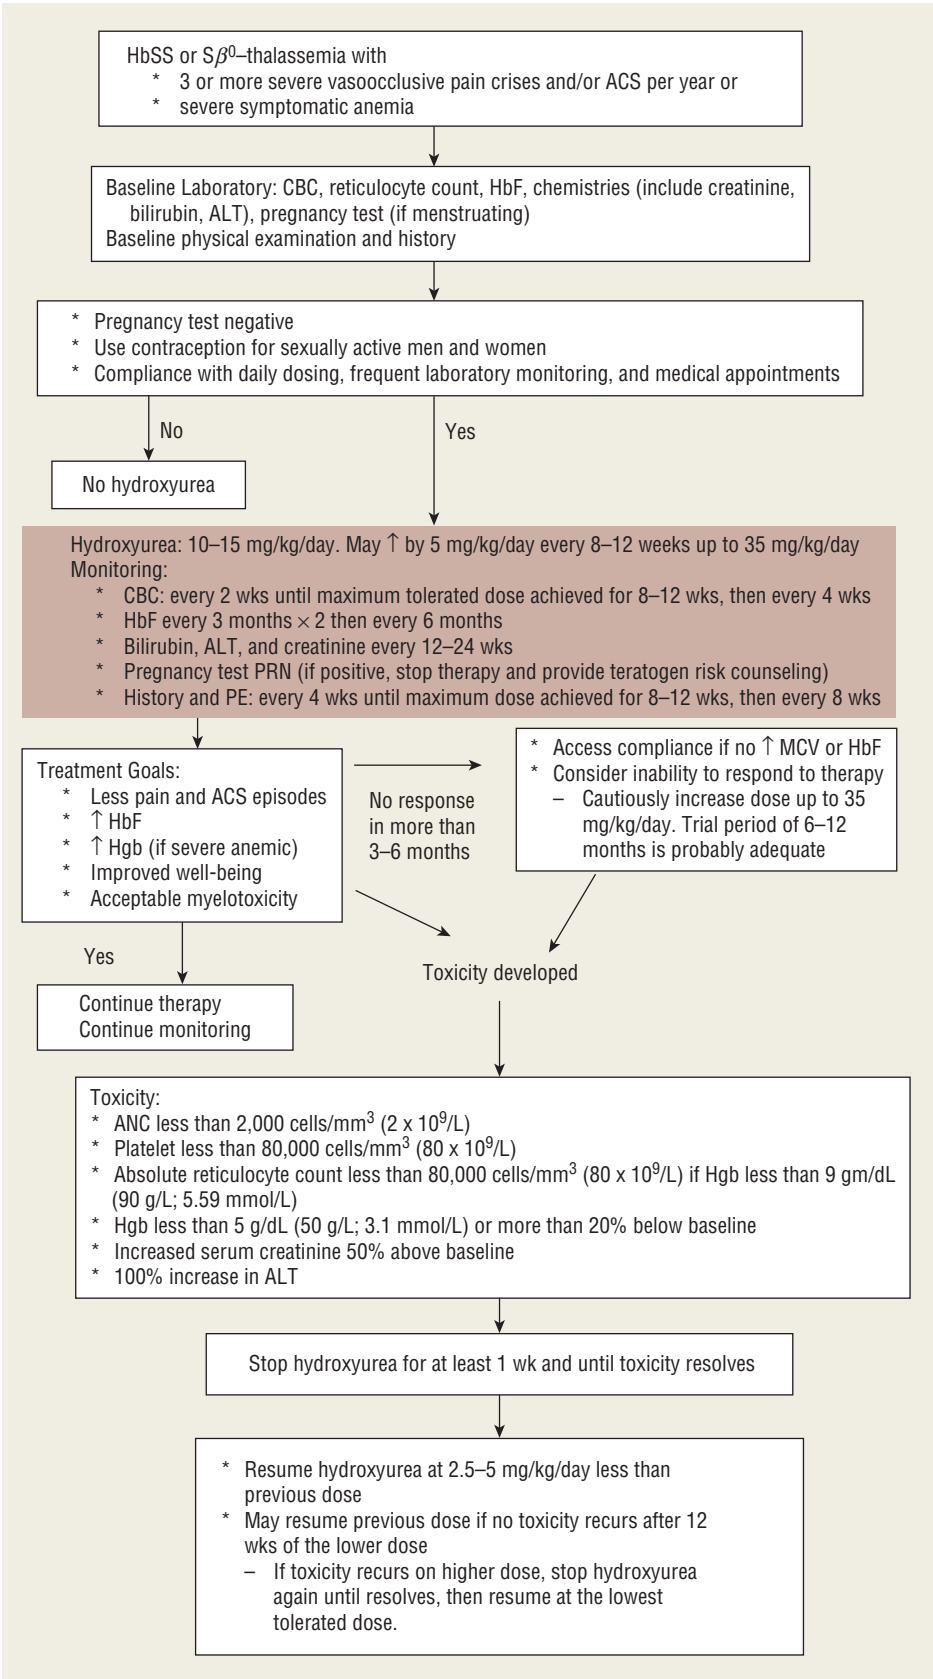

FIGURE 111-6. Hydroxyurea use in sickle cell disease. (ACS, acute chest syndrome; ALT, alanine aminotransferase; ANC, absolute neutrophil count; CBC, complete blood cell count; HbF, fetal hemoglobin; Hb, hemoglobin; HbSS, homozygous sickle cell hemoglobin; HBSSβ^0, sickle cell β^0-thalassemia; MCV, mean corpuscular volume; PE, physical examination; PRN, as needed; RBC, red blood cell.) *(From Stuart et al.,[7] Sickle Cell Disease Care Consortium,[46] and Halsey and Roberts.[51])*

use in these patients cannot be recommended. When used in combination with hydroxyurea, erythropoietin increases HbF levels to a greater extent than hydroxyurea alone. Erythropoietin has also been used in combination with decitabine. Other proposed combinations are hydroxyurea combined with butyrate or decitabine, based on their different mechanisms of action.[4,11,63,66]

CHRONIC TRANSFUSION THERAPY

Transfusions play an important role in the management of SCD. In acute illness, transfusions can be life saving and will be discussed in a later section. Maintenance transfusion programs are used to prevent serious complications of SCD. The primary indication for chronic transfusion is stroke prevention and amelioration of other organ damage. Transfusion can be done by simple or exchange transfusions. Exchange transfusion is associated with higher cost but has the advantage of limiting volume and minimizing hyperviscosity and iron overload.[4,5,67]

6 In children who had a stroke, chronic transfusions can reduce stroke recurrence from about 50% to about 10% over 3 years. As the initial stroke in SCD can be devastating, transfusions are usually given to prevent the initial stroke. In one trial, prophylactic transfusions significantly reduced the incidence of first stroke over a 2-year period in children 2 to 16 years of age with abnormal TCD ultrasonography. Stroke occurrence rate was reduced from 16% in patients receiving usual care to 2% in those who received prophylactic transfusions.[67–69]

Chronic transfusions can also reduce the risk of vasoocclusive pain and acute chest syndrome, and prevent or delay progression of organ damage. They can also reverse preexisting organ dysfunction and improve quality of life, energy levels, exercise tolerance, growth, and sexual development. Selected patients in whom chronic transfusions should be considered are patients with transient ischemic attack, abnormal TCD, severe or recurrent acute chest syndrome, debilitating pain, splenic sequestration, recurrent priapism, chronic organ failure, intractable leg ulcers, severe chronic anemia with cardiac failure, and complicated pregnancies.[5,9,68,70]

The goal of transfusions is to achieve and maintain an HbS concentration of less than 30% of total hemoglobin. Transfusions are usually given every 3 to 4 weeks, but the frequency of transfusion is adjusted to maintain the desired HbS levels. After 4 years of therapy without development of complications, many clinicians give transfusions less frequently and allow the HbS concentration to increase to 50% of total hemoglobin.[9,67] The optimal duration of chronic primary prophylactic transfusion therapy is not clear, but discontinuation of transfusions has been associated with a 50% recurrence rate within 12 months and abnormal blood flow velocity in children. For secondary prevention, current recommendations are to continue transfusion for at least 5 years if there has been no neurologic event and imaging studies have been normalized or until age 18 years. A pilot study suggests that hydroxyurea should be started prior to discontinuation of transfusion for secondary stroke prevention.[9,67–72]

Although the benefits of transfusion therapy are clear in some clinical situations, its role in other situations such as priapism and leg ulcer remains controversial.[67] The risks of transfusion therapy must be weighed against possible benefits. The risks associated with transfusion therapy include alloimmunization (sensitization to the blood received), hyperviscosity, viral transmission, volume overload, iron overload, and transfusion reactions. Alloimmunization occurs in 18% to 36% of SCD patients who receive blood transfusions. The use of leukocyte-reduced RBC transfusions or human leukocyte antigen (HLA)-matched units in chronically transfused patients can reduce the risk of alloimmunization. Transfusion-related infections also remain a concern. All patients should be immunized with hepatitis A and B vaccines. Other viruses that can be transmitted through blood products are parvovirus B19, hepatitis C, and cytomegalovirus (CMV). The risk of contracting acquired immune deficiency syndrome (AIDS) from blood transfusions, although still of concern, has decreased with routine blood screening.[5,24,67] Iron overload is another complication of transfusions, and patients should be counseled to avoid excess dietary iron. Abnormal liver biopsy results showing mild to moderate inflammation or fibrosis have been reported. Chelation therapy should be considered after more than 1 year of chronic transfusions or when serum ferritin is greater than 1,500 to 2,000 ng/mL (1,500 to 2,000 mcg/L).[5,9,11,67] Deferoxamine has been associated with oto- and ocular toxicity and growth failure. Therefore, patients receiving chelation therapy should have yearly ophthalmologic and auditory examinations. Deferasirox, an oral chelator given once daily, has shown effectiveness in management of iron overload in SCD. The most common side effects with deferasirox are transient gastrointestinal symptoms such as nausea, vomiting, abdominal pain, and skin rash.[5,9,73–75]

Unique to the population with SCD is a constellation of features that can occur in response to blood transfusion; this is often referred to as the sickle cell hemolytic transfusion reaction syndrome. This syndrome includes manifestations of an acute or delayed transfusion reaction caused by alloimmunization. Delayed reactions can occur 2 to 20 days after transfusion. During the hemolytic reaction, the patient develops symptoms suggestive of a pain crisis, or symptoms worsen if the patient is already in crisis. The patient can also develop an anemia posttransfusion that is more severe than previously observed because of the rapid decline in hemoglobin and hematocrit, accompanied by a suppressed erythropoiesis. Reticulocytopenia is often seen in delayed hemolytic transfusion reactions. Alloantibodies and autoantibodies that formed as a result of past transfusions can serve as a trigger, causing a return of symptoms in the postrecovery period. Subsequent transfusions can further worsen the clinical situation because of the presence of autoimmune antibodies. Life-threatening events can be treated with steroids and intravenous immunoglobulin. Erythropoietin has been used in patients with reticulocytopenia. Recovery, as evidenced by reticulocytosis with a gradual increase in the hemoglobin level, may occur only after further transfusions are withheld. Although some patients tolerate further transfusions after recovery, others experience a recurrence of the hemolytic transfusion reaction. To prevent recurrent hemolytic anemia, rituximab has been used with success in SCD patients with a prior history of a life-threatening event.[9,14,67,76]

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Allogeneic hematopoietic stem cell transplantation (HSCT) is currently the only therapy that can cure patients with SCD.[77–79] The overall survival rate and event-free survival rate reported in three studies in children and young adults were 92% to 94% and 83% to 86%, respectively. The largest series was reported in 87 patients age 2 to 22 years with severe SCD. Transplant-related deaths occurred in six patients, with graft-versus-host disease (GVHD) being the main cause of death in four patients.[78] The reported incidences of acute and chronic GVHD ranged from 15% to 20% and 12% to 20%, respectively. Other complications included seizure, marrow rejection, and sepsis. Improved growth, stabilization or improvement of CNS abnormalities, and recovery of splenic dysfunction were observed in post-transplant SCD patients, but gonadal failure and delayed sexual development in females requiring hormonal replacements have been reported.[77,79,80]

The best candidates for allogeneic HSCT are SCD patients who are younger than 16 years of age; have severe complications such

as refractory pain, stroke, or recurrent acute chest syndrome; and have an HLA-matched donor. Although allogeneic HSCT in young children before organ damage and alloimmunization occur can be associated with an increased success rate, disease progression is unpredictable, making it difficult to determine the optimal time for transplantation. The risks associated with allogeneic HSCT must be carefully considered, as the transplant-related mortality rate is about 5% to 10%, and graft rejection is about 10%. Other risks associated with allogeneic HSCT include secondary malignancies. Neurologic events, such as intracranial hemorrhage and seizures during transplant, were seen more frequently in patients with a history of stroke.[9,77,79]

Experience with unrelated HLA-matched or related HLA-mismatched donor transplants is very limited. Studies in thalassemia patients do not support the use of these alternate donors at this time. Umbilical cord blood is another donor source. Its advantages include a lower incidence of severe GVHD and the potential of using umbilical cord blood from unrelated donors, but such advantages are balanced by longer duration for engraftment and a higher rate of graft rejection.[5,77,79,81] Finally, a recent study reports the use of nonmyeloablative allogeneic stem-cell transplantation in 10 adult patients to achieve mixed donor-recipient chimerism and reversal of SCD.[82]

TREATMENT OF COMPLICATIONS

GENERAL MANAGEMENT

Parents and older children should be educated on the signs and symptoms of complications and conditions that require urgent evaluation. During acute illness, patients should be evaluated promptly, as deterioration can occur rapidly. It is essential to maintain a balanced fluid status because dehydration and fluid overload can worsen complications associated with SCD. Oxygen saturation by pulse oximetry should be maintained at least 92% or at baseline. New or increasing supplemental oxygen requirements should be investigated.[5,8,9,11]

EPISODIC TRANSFUSIONS FOR ACUTE COMPLICATIONS

Indications for RBC transfusions include (a) acute exacerbation of baseline anemia, such as aplastic crisis if the anemia is severe, hepatic or splenic sequestration, or severe hemolysis; (b) severe vasoocclusive episodes, such as acute chest syndrome, stroke, or acute multiorgan failure; and (c) preparation for procedures that require the use of general anesthesia or ionic contrast. Other patients in whom transfusions can be useful include patients with complicated obstetric problems, refractory leg ulcers, or refractory and protracted painful episodes or severe priapism. Simple transfusion or partial exchange transfusion can be used. If simple transfusion is used, volume overload leading to congestive heart failure can occur if anemia is corrected too rapidly in patients with severe anemia. In addition, increases in hemoglobin levels to greater than 10 to 11 g/dL (100 to 110 g/L; 6.21 to 6.83 mmol/L) can cause hyperviscosity and should be avoided.[5,9,67]

INFECTION AND FEVER

Patients with SCD should be evaluated as soon as possible for any fever greater than 38.5°C (101.3°F). Criteria for hospitalization include an infant younger than 1 year old, history of previous bacteremia or sepsis, temperature greater than 40°C (104°F), WBC greater than 30,000 cells/mm^3 (30 × 10^9/L) or less than 5,000 cells/mm^3 (5 × 10^9/L) and/or platelets less than 100,000 cells/mm^3 (100 × 10^9/L), and evidence of other acute complications or toxic appearance. Outpatient management can be considered in older nontoxic children with reliable family caregivers. Antibiotic choice should provide adequate coverage for encapsulated organisms.

7 Ceftriaxone should be used for outpatient management because it provides coverage for 24 hours. If admitted, cefotaxime can also be used. For patients with cephalosporin allergy, clindamycin can be used. Vancomycin should be considered for acutely ill children or if *Staphylococcus* is suspected. A macrolide antibiotic should be added if *Mycoplasma pneumoniae* is suspected. Penicillin prophylaxis should be discontinued while the patient is receiving broad-spectrum antibiotics. Acetaminophen or ibuprofen can be used for fever control. Increased fluid requirements can be needed because of dehydration and/or increased insensible loss.[1,5,9,11,24]

CEREBROVASCULAR ACCIDENTS

Patients with acute neurologic events must be hospitalized and monitored closely. Physical and neurologic examination should be performed every 2 hours. Acute treatment for children should include exchange transfusion or simple transfusion to maintain hemoglobin at about 10 g/dL (100 g/L; 6.21 mmol/L) and HbS less than 30%, anticonvulsants for patients with a seizure history, and therapy for increased intracranial pressure if needed. Chronic transfusion therapy should be initiated for children with ischemic stroke as discussed earlier. In adults presenting with ischemic stroke, thrombolytic therapy should be considered if it is less than 3 hours since the onset of symptoms.[9,11,25,27,68]

ACUTE CHEST SYNDROME

Patients with acute chest syndrome should use incentive spirometry frequently (e.g., at least every 2 hours while awake) to reduce atelectasis development. In addition, proper management of pain is important. The goal is to provide relief while avoiding analgesic-induced hypoventilation. Appropriate fluid therapy is important as overhydration can cause pulmonary edema and exacerbate respiratory distress. Early use of broad-spectrum antibiotics, including a macrolide or quinolone, is also recommended. Studies indicate that infection is common with acute chest syndrome and can involve gram-positive, gram-negative, or atypical bacteria. Oxygen therapy is indicated for all patients who are hypoxic or in acute distress. In a patient with a history of reactive airway disease or wheezing on examination, a trial of bronchodilators is appropriate. Transfusions are often used in the treatment of acute lung disease.[1,5,9,11,31]

Steroids can decrease inflammation and endothelial cell adhesion. Glucocorticoids can decrease the duration of hospitalization, transfusions, and need for other supportive care but can increase the readmission rate for SCA-related complications.[83] Another promising therapy is the use of NO, which relaxes and dilates blood vessels. Its hematologic effects include inhibition of platelet aggregation and reduction in the polymerization tendency of HbS. Marked improvement of pulmonary status and cardiac output has been reported in a patient with acute chest syndrome. Both inhaled NO and oral L-arginine, the precursor of NO, are being evaluated for management of acute chest syndrome.[3,4,31]

PRIAPISM

Stuttering priapism, episodes that last a few minutes to 2 hours, resolve spontaneously. Prolonged episodes lasting more than 2 to

3 hours require prompt medical attention. The initial goals of treatment are to provide appropriate analgesic therapy, reduce anxiety, produce detumescence, and preserve testicular function and fertility. Treatment given within 4 to 6 hours can usually reduce erection. Aggressive hydration and adequate pain control should be initiated. Use of ice packs is not recommended. Heat (hot water bottles, hot packs, or sitz baths) can provide comfort without precipitating pain crisis. Although transfusions have been given to these patients, the efficacy of this therapeutic intervention has not been established.[1,9,33,84]

Clinicians have used both vasoconstrictors and vasodilators in the treatment of priapism. Vasoconstrictors, such as diluted phenylephrine (10 mcg/mL) or epinephrine (1:1,000,000), are thought to work by forcing blood out of the corpus cavernosum into the venous return. In one uncontrolled open-label study, aspiration followed by intrapenile irrigation with epinephrine was effective and well tolerated. In that study, blood was first aspirated from the corpus cavernosum, and then the area was irrigated with a 1:1,000,000 solution of epinephrine. The priapism resolved in 37 of the 39 occasions. A follow-up study reported that 3 out of 20 patients required a repeat procedure within 24 hours. The therapy was well tolerated with no serious immediate or long-term side effects, but on two occasions, a small intrapenile hematoma formed after treatment.[33,84]

Vasodilators, such as terbutaline and hydralazine, relax the smooth muscle of the vasculature. This relaxation allows oxygenated arterial blood to enter the corpus cavernosum, which displaces or washes out the damaged sickle cells that are stagnant in the corpus cavernosum. Terbutaline has been used to treat priapism, but it has not been formally studied in patients with SCA. In one case report, a single oral sildenafil dose at onset of priapism aborted episodes. Surgical interventions used in severe refractory priapism have included a variety of shunt procedures. These surgical procedures have been successful in some cases, but they have a high failure rate and potential serious complications, which include impotence, skin sloughing, cellulitis, and urethral fistulas.[9,11,33,84]

Modalities to prevent priapism are limited and not well studied. Pseudoephedrine (30 or 60 mg/day given orally at bedtime) and leuprolide, a gonadotropin-releasing hormone, have been used to decrease the number of recurrent episodes of priapism. Hydroxyurea therapy can also be useful. Finally, antiandrogens (bicalutamide, and finasteride) and sildenafil have been used in SCD for treatment of recurrent or refractory priapism without major side effects. The role of RBC transfusion in preventing priapism remains unclear.[4,9,11,33,67,84,85]

CURRENT CONTROVERSY

Some clinicians transfuse patients to maintain an HbS level less than 30% to prevent recurrent priapism. Duration of such regimens should be limited to 6 to 12 months.

MANAGEMENT OF CRISIS

Aplastic Crisis

Treatment of aplastic crisis is primarily supportive, and most patients recover spontaneously. The patient can need blood transfusions if the anemia is severe or symptomatic. The reticulocyte count can determine if there is red cell production and the need for transfusions. The most common cause for aplastic crisis is acute infection with human parvovirus B19. As parvovirus is contagious, infected patients should be placed in isolation. In addition, contact with pregnant healthcare providers should be avoided because parvovirus infection during the midtrimester of pregnancy can result in hydrops fetalis and stillbirth.[5,9,11]

Sequestration Crisis

Splenic sequestration crisis is a major cause of mortality in young patients with SCD. The sequestration of RBCs in the spleen can result in a rapid drop of hematocrit, leading to hypovolemia, shock, and death. Immediate treatment is RBC transfusion to correct hypovolemia. Broad-spectrum antibiotic therapy, which includes coverage for pneumococci and *H. influenzae*, can also be beneficial because infection can precipitate crises.[5,9,11]

Recurrent episodes occur in about half of patients and are associated with increased mortality. Options for management of recurrence include observation, chronic transfusion, and splenectomy. Adults are often observed because they tend to have milder episodes. Increased risk of invasive infection after splenectomy is a concern in young children. Chronic transfusions delay splenectomy and temporarily restore splenic function, but it is associated with its own risks. Splenectomy is probably indicated, even after a single sequestration crisis, if that event is life threatening. Splenectomy should be considered after repetitive episodes, even if they are less serious. For children younger than 2 years of age, chronic blood transfusions are recommended to prevent sequestration and delay splenectomy until the age of 2 years, when there is less risk of postsplenectomy septicemia. Finally, splenectomy should also be considered for patients with chronic hypersplenism.[5,9,11,86]

Vasoocclusive Pain Crisis

Hydration and analgesia are the mainstays of treatment for vasoocclusive (painful) crises (Table 111–4). Patients with mild pain crisis can be treated as outpatients with rest, increased fluid intake, warm compresses, and oral analgesics. Hospitalization is necessary for moderate to severe crisis. As infection can precipitate crises, an infectious etiology should be ruled out, and appropriate empiric therapy should be initiated in patients who have fever or are critically ill. In anemic patients, transfusion to maintain the hemoglobin level at baseline can be needed. Fluid replacement given intravenously or orally at 1.5 times the maintenance requirement is recommended. Close monitoring of fluid status is essential as aggressive hydration, particularly with sodium-containing fluids, can lead to volume overload, acute chest syndrome, and heart failure.[1,3,5,9,11]

The frequency and severity of acute pain episodes associated with SCD are variable, and pain should be assessed, and analgesic therapy should be tailored for each patient. Several pain assessment tools are available and should be used to measure the intensity of pain. Unfortunately, they have not been validated for sickle cell pain. The healthcare provider should choose one tool appropriate for age and use it routinely to assess pain. Other useful information to guide choice of analgesics should include previous effective agents and their dosages, response to therapy and previous clinical course, and duration of pain crisis.[5,9,11,87,88]

8 Aggressive therapy that relieves pain and enables the patient to attain maximum functional ability should be initiated in patients with pain crisis. Treatment of mild to moderate pain should include the use of nonsteroidal antiinflammatory drugs (NSAIDs) or acetaminophen, unless there are contraindications to their use. Ketorolac is useful for patients requiring intravenous therapy. Because of concerns about gastrointestinal bleeding, it is recommended to limit the duration of therapy to 5 days or less. When acetaminophen is used, it is important to review the total dose of acetaminophen administered in patients who may also be receiving

TABLE 111-4 Management of Acute Pain of Sickle Cell Disease

Principles
• Treat underlying precipitating factors
• Avoid delays in analgesia administration
• Use pain scale to assess severity
• Choice of initial analgesic should be based on previous pain crisis pattern, history of response, current status, and other medical conditions
• Schedule pain medication; avoid as-needed dosing
• Provide rescue dose for breakthrough pain
• If adequate pain relief can be achieved with one or two doses of morphine, consider outpatient management with a weak opioid; otherwise hospitalization is needed for parenteral analgesics
• Frequently assess to evaluate pain severity and side effects; titrate dose as needed
• Treating adverse effects of opioids is part of pain management
• Consider nonpharmacologic intervention (e.g., relaxation techniques, guided imagery, deep breathing)
• Transition to oral analgesics as the patient improves; choose an oral agent based on previous history, anticipated duration, and ability to swallow tablets; if sustained-release products are used, a product with a rapid onset is also needed for breakthrough pain
Analgesic regimens
Mild-to-moderate pain: nonopioid ± weak opioid
Moderate-to-severe pain: weak opioid or low dose of a strong opioid ± nonopioid
Severe pain: strong opioid + nonopioid
Weak opioid
Acetaminophen with codeine
Dose based on codeine–children: 1 mg/kg per dose every 6 hours; adult: 30 to 60 mg/dose
Hydrocodone + acetaminophen
Dose based on hydrocodone–children: 0.2 mg/kg per dose every 6 hours; adults: 5 to 10 mg/dose
Nonopioid
Oral antiinflammatory agents
Use with caution in patients with renal failure (dehydration) and bleeding
Ibuprofen–children: 10 mg/kg every 6 to 8 hours; adult: 200 to 400 mg/dose
Naproxen: 5 mg/kg every 12 hours; adult 250 to 500 mg/dose
Intravenous antiinflammatory agents:
Ketorolac: 0.5 mg/kg up to 30 mg/dose every 6 hours
Strong opioid
Morphine: 0.1 to 0.15 mg/kg per dose every 3 to 4 hours for children; 5 to 10 mg/ dose for adults
Continuous infusion: 0.04 to 0.05 mg/kg per hour; titrate to effect
Hydromorphone: 0.015 mg/kg per dose every 3 to 4 hours for children; 1.5 to 2 mg/dose for adults
Continuous infusion: 0.004 mg/kg per hour; titrate to effect
Patient-controlled analgesics:
Morphine: 0.01 to 0.03 mg/kg per hours basal; demand 0.01 to 0.03 mg/kg every 6 to 10 min; 4-hour lock out 0.4 to 0.6 mg/kg
Hydromorphone: 0.003 to 0.005 mg/kg per hour basal; demand 0.03 to 0.05 mg/kg every 6–10 minutes; 4 hour lock out 0.06 to 0.08 mg/kg
Rescue therapy:
For breakthrough, give 1/4 to 1/2 of the scheduled dose as bolus every 1 to 2 hour; assess amount of rescue dose used in 8 to 12 hours and readjust scheduled dose or infusion rate as needed
Other adjunct therapy:
Hydration, heating pads, relaxation, and distraction
Stool softener and/or stimulants for constipation
Antihistamine for itching
Antiemetics for nausea or vomiting

From Montalembert,[1] Driscoll,[5] National Institutes of Health,[9] Stuart and Nagel,[11] Richard,[87] Dumaplin.[88]

the agent for fever or another acetaminophen-containing product for pain. If mild to moderate pain persists, an opioid should be added. Effective combination therapy, such as an NSAID combined with an opioid, can enhance analgesic efficacy while decreasing side effects.[5,9,11,87,88]

Severe pain should be treated aggressively until the pain is tolerable. Commonly used opioids include morphine, hydromorphone, fentanyl, and methadone. The weak opioids, codeine and hydrocodone, are used to manage mild to moderate pain. Meperidine has no advantages as an analgesic. Its duration of action is short compared with the half-life of the metabolite normeperidine. The accumulation of normeperidine can cause central nervous system side effects, ranging from dysphoria to seizures. Therefore, meperidine should be avoided if possible and used only for a very brief duration in patients who are allergic or intolerant to other opioids.[9,11,87,88]

Both prior history and current assessment should be considered in the management of pain crisis. For patients whose typical crisis improves in a short time, preparations with a short duration of action are appropriate. For patients whose crises require many days to resolve, sustained-release preparations combined with a short-acting product for breakthrough pain are more appropriate. If the patient has been on long-term opioid therapy at home, tolerance can develop. In these cases, the pain of acute crises can be treated with a different potent opioid or a larger dose of the same medication. Intravenous administration provides a rapid onset of action and therefore is preferred for severe pain. Intramuscular injections should be avoided. Children might actually deny pain because of fear of injections. Analgesics should be titrated to pain relief. In patients with continuous pain, the analgesic should be given as a scheduled dose or continuous infusion. Continuous infusion has the advantage of less fluctuation of blood levels between dosing intervals. As-needed dosing is only appropriate for breakthrough pain. Patient-controlled analgesia (PCA) is commonly used. When used properly, PCA allows patients to have control over pain therapy and minimizes the lag time between perception of pain and administration of analgesics. The transdermal fentanyl patch has also been used successfully, but its role in sickle cell pain crisis is unclear because of its long time of onset of pain relief (12 to 16 hours) and fixed dosage form, which makes it difficult to titrate the dose. Other alternative pain management techniques such as physical therapy and relaxation therapy can be helpful as adjunct therapy.[9,11,87–89]

Suboptimal pain relief has been reported in both emergency room and hospitalized patients. The most common cause of suboptimal pain control in children with SCA is the suspicion of addiction. This obstacle is especially common in adolescents. In one study, 53% of emergency physicians believed that 20% of SCD patients are addicted to analgesics. Another barrier for effective pain control is the difference in perception between patients, family, and healthcare providers. Patients with SCD often suffer from chronic pain, and they may cope with the pain by being inactive. Patients who have inadequate pain control can exhibit anxiety and drug-seeking behavior for fear of pain. Tolerance to narcotics can also be misinterpreted as drug addiction by healthcare providers and families. Aggressive pain control, frequent monitoring of pain during crises, and tapering medication according to response are factors that minimize physical dependence. The use of a protocol has been shown to result in optimal management of pain control in SCD.[87,88,90,91]

Intracellular adhesion of RBCs contributes to vasoocclusion in SCD. Agents that can alter adhesion molecules on RBCs can potentially reduce or ameliorate clinical manifestation of SCD. Omega-3 fatty acids are important components of cell membranes and organelles and may be important for erythrocyte integrity and play a role in reducing hemolysis. In addition, omega-3 fatty acids have antiadhesion activity by modulating adhesive molecules in the membrane. Reduction of disease severity has been reported in clinical trials.[92]

PHARMACOECONOMIC CONSIDERATIONS

Patients with SCD incur considerable healthcare costs. Pharmacoeconomic considerations should include newborn screening, cost of managing acute and chronic complications, and the economic impact of new treatment modalities. Early penicillin prophylaxis prevents pneumococcal sepsis in infants. Newborn screening targeted at African Americans has been shown to be cost-effective. Whether it is cost-effective to screen all infants depends on the prevalence of high-risk infants in the area. In general, universal screening identifies more infants with disease, prevents more deaths, and can provide for a certain degree of cost-effectiveness because targeted screening might not detect all infants with the disease.[2,93]

Hospitalization is an important societal financial burden. Studies conducted in various regions have shown that a small number of patients consume a disproportionate amount of care as a result of severe illness, and most of the total cost is related to hospitalizations. In 2004, an estimated 113,098 patients with SCD were hospitalized, of whom, about three-quarters were adult patients. The average cost for each hospitalization was $6,223, and the total estimated cost was $488 million.[94] Patients who are not being followed in settings that provide comprehensive medical care tend to acquire higher costs for emergency room and hospital visits. A study examining relationships between socioeconomic factors and geographic distribution in Alabama reported that use of comprehensive care was lower for those living in rural areas.[95–97]

Newer therapies, diagnostic methods such as TCD, and chronic transfusions further increase cost. The estimated mean cost in SCD patients receiving iron chelation was $69,259 per year.[98] Using the data from the MSH trial, researchers estimated the average annual cost for medical care to be lower in the hydroxyurea group as compared with the placebo group ($12,160 vs. $22,020). Hospitalization for pain crisis accounted for the highest cost in both groups, and savings of more than $5,000 per patient per year of medical costs could be achieved if every eligible patient received the agent. However, this cost-saving was not demonstrated in one analysis performed in Maryland.[98,99] Allogeneic HSCT can potentially cure the disease and if successful can reduce long-term costs, but it requires a high up-front cost. New therapies, although expensive, might reduce visits to emergency departments and inpatient hospitalizations, improving the cost-effectiveness of those therapies over a patient's lifetime.[9]

EVALUATION OF THERAPEUTIC OUTCOMES

9 SCD is a complex disorder that requires multidisciplinary comprehensive care. All patients should be medically evaluated regularly to establish baseline, monitor changes, and provide education appropriate for age. For infants younger than 1 year old, medical evaluations every 2 to 4 months are needed. Beyond 1 year of age, evaluation can be extended to every 6 to 12 months with modifications depending on severity of the illness.[5,9]

It is important to establish baseline laboratory values and imaging studies. Routine laboratory evaluation includes complete blood cell counts and reticulocyte counts every 3 months up to 2 years of age, then every 6 months; HbF level should be taken every 6 months until 2 years of age, then annually. Evaluation of renal, hepatobiliary, and pulmonary function should be done annually. TCD screening is recommended to start at age 2 years, then annually. Ophthalmologic examination to screen for retinopathy is recommended at around age 10 years. In patients with recurrent acute chest syndrome, pulmonary function tests should be done to establish baseline values and identify declines in lung function.

It is essential that immunizations and prophylactic antibiotics are given. When infections do occur, appropriate antibiotic therapy should be initiated, and the patient should be monitored for laboratory and clinical improvement. The efficacy of hydroxyurea can best be assessed in terms of the decrease in number, severity, and duration of sickle cell pain crises. HbF concentrations or MCV values can also provide some indication of the patient's response to therapy. When painful crises do occur, the effectiveness of analgesics can be measured by subjective assessments made by the patient, family, and healthcare practitioners. The success of post-stroke blood transfusions can be measured by clinical progression or the occurrence of subsequent strokes.

CONCLUSIONS

The goals of the general management of SCA are to decrease the number of sickle cell crises, decrease the complications arising from the disease, and improve the overall quality of the patient's life. The general care of SCA patients still includes early penicillin prophylaxis and appropriate immunization. HbF inducers such as hydroxyurea can decrease the frequency and severity of painful episodes. Continued studies of other possible agents and treatment modalities that can reduce crises or reverse organ damage are warranted.

ABBREVIATIONS

ASPEN syndrome: association of sickle cell disease, priapism, exchange transfusion, and neurologic events

HbA: hemoglobin A

HbAS: one normal (hemoglobin A) and one sickle cell hemoglobin (hemoglobin S) gene

HbC: hemoglobin C

HbF: fetal hemoglobin

HbSβ^+-thal, HbSβ^0-thal: hemoglobin sickle cell β^+-thalassemia and hemoglobin sickle cell β^0-thalassemia

HbSC: sickle cell hemoglobin C

HbSS: homozygous sickle cell hemoglobin (hemoglobin S)

HbS: sickle cell hemoglobin

HLA: human leukocyte antigen

HSCT: hematopoietic stem cell transplantation

ISC: irreversibly sickled cell

MCHC: mean corpuscular hemoglobin concentration

MCV: mean corpuscular volume

MSH: Multicenter Study of Hydroxyurea in Sickle Cell Anemia

NO: nitric oxide

NSAID: nonsteroidal antiinflammatory drug

PCA: patient-controlled analgesia

PCV7: 7-valent pneumococcal conjugate vaccine

PPV 23: 23-valent pneumococcal polysaccharide vaccine

RBC: red blood cell

SCA: sickle cell anemia

SCD: sickle cell disease

SCT: sickle cell trait

TCD: transcranial Doppler

WBC: white blood cell

CHAPTER 112

Drug-Induced Hematologic Disorders

CHRISTINE N. HANSEN AND AMY F. ROSENBERG

KEY CONCEPTS

1. The most common drug-induced hematologic disorders include aplastic anemia, agranulocytosis, megaloblastic anemia, hemolytic anemia, and thrombocytopenia.
2. Drug-induced hematologic disorders are generally rare adverse effects associated with drug therapy.
3. Reporting during postmarketing surveillance of a drug is usually the method by which the incidence of rare adverse drug reactions is established.
4. Because drug-induced blood disorders are potentially dangerous, rechallenging a patient with a suspected agent in an attempt to confirm a diagnosis may not be ethical.
5. The mechanisms of drug-induced hematologic disorders are the result of direct toxicity or an immune reaction.
6. The primary treatment of drug-induced hematologic disorders is removal of the drug in question and symptomatic support of the patient.
7. Frequent laboratory monitoring may be warranted for agents commonly demonstrating severe hematologic reactions.

1 Hematologic disorders have long been a potential risk of modern pharmacotherapy. Granulocytopenia (agranulocytosis) was reported in association with one of medicine's early therapeutic agents, sulfanilamide, in 1938.[1] Some agents cause predictable hematologic disease (e.g., antineoplastics), but others induce idiosyncratic reactions not directly related to the drugs' pharmacology. The most common drug-induced hematologic disorders include aplastic anemia, agranulocytosis, megaloblastic anemia, hemolytic anemia, and thrombocytopenia.

2 The incidence of idiosyncratic drug-induced hematologic disorders varies depending on the condition and the associated drug. Few epidemiologic studies have evaluated the actual incidence of these adverse reactions, but these reactions appear to be rare. A multinational study in Latin American countries estimated the incidence of agranulocytosis was 0.38 cases per 1 million inhabitant-years and reported a rate of 1.6 cases of aplastic anemia per million per year.[2,3] Similar results were reported in epidemiologic studies conducted in Thailand and Barcelona.[4,5] The incidence of drug-induced thrombocytopenia is more frequent, with some reports suggesting that as many as 5% of patients who receive heparin develop heparin-induced thrombocytopenia.[6]

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Although drug-induced hematologic disorders are less common than other types of adverse reactions, they are important because they are associated with significant morbidity and mortality. An epidemiologic study conducted in the United States estimated that 4,490 deaths in 1984 were attributable to blood dyscrasias from all causes. Aplastic anemia was the leading cause of death, followed by thrombocytopenia, agranulocytosis, and hemolytic anemia.[7] Like most other adverse drug reactions, drug-induced hematologic disorders are more common in the elderly than in the young; the risk of death also appears to be greater with increasing age. The risk of agranulocytosis has been reported to be higher in women than in men, with some studies suggesting a biphasic distribution, with peaks in patients <10 years of age and those >60 years of age.[3]

3 Because of the seriousness of drug-induced hematologic disorders, it is necessary to track the development of these disorders to predict their occurrence and to estimate their incidence. Reporting during postmarketing surveillance of a drug is the most common method of establishing the incidence of adverse drug reactions. The MedWatch program supported by the Food and Drug Administration is one such program.[8] Many facilities have similar drug-reporting programs to follow adverse drug reaction trends and to determine whether an association between a drug and an adverse drug reaction is causal or coincidental. In the case of drug-induced hematologic disorders, these programs can enable practitioners to confirm that an adverse event is indeed the result of drug therapy rather than one of many other potential causes; general guidelines are readily available.[9,10]

4 Because drug-induced blood disorders are potentially dangerous, rechallenging a patient with a suspected agent in an attempt to confirm a diagnosis may not be ethical. In vitro studies with the offending agent and cells or plasma from the patient's blood can be performed to determine causality.[11] These methods are often expensive, however, and require facilities and expertise that are not generally available. Therefore, it is extremely important that practitioners be able to clinically evaluate suspect drugs quickly and to interrupt therapy when necessary.

Throughout the past decades, lists of drugs that have been associated with adverse events have been developed to help clinicians identify possible causes. Unfortunately, these lists are comprehensive and include commonly used drugs, making it difficult to determine the cause of any abnormality. Furthermore, the absence of a drug from such a list should not discourage the investigation and reporting of an agent associated with an adverse event. It is imperative that clinicians use a rational approach to determine causality and identify the agents associated with a reaction. The clinician should focus on the issue, perform a rigorous investigation, develop

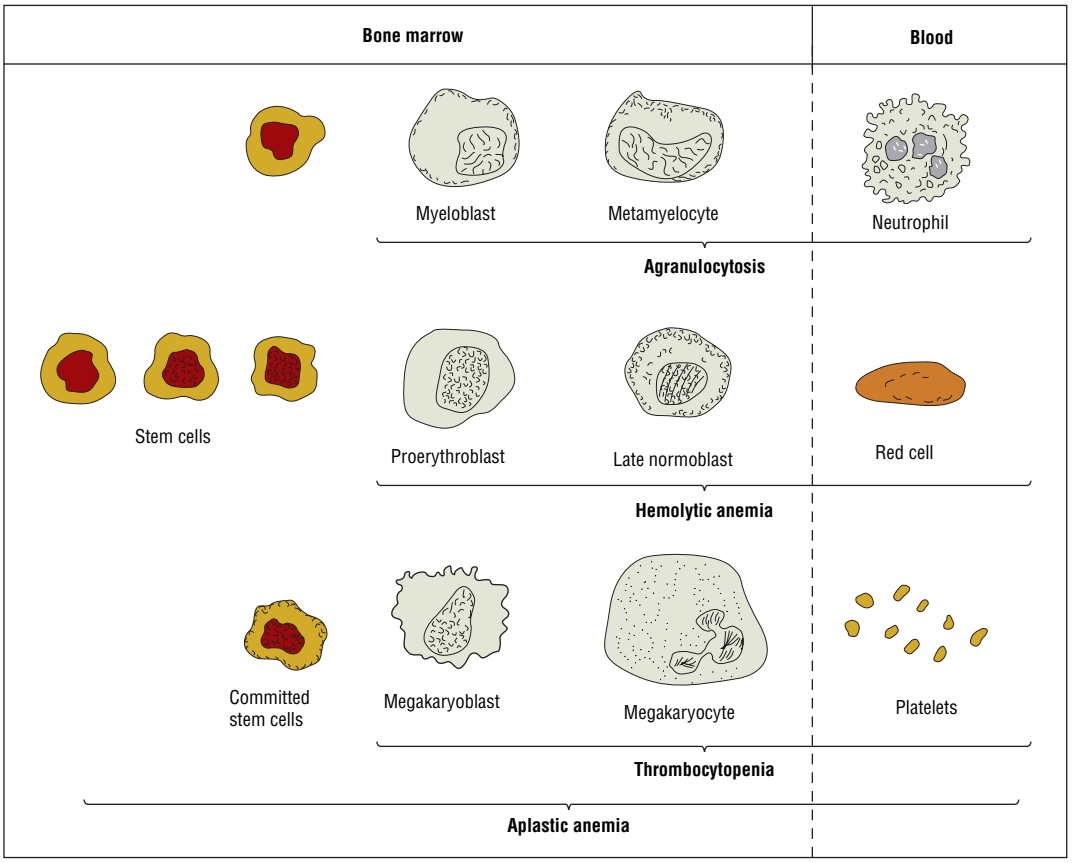

FIGURE 112-1. Differentiation of the stem cell into committed cell lines, illustrating the origins of various drug-induced hematologic disorders.

appropriate criteria, use objective criteria to grade the response, and complete a quantitative summary. A systematic approach to evaluate the information available in the literature also helps the clinician to focus and intervene in the cause of the disorder.

A common tool employed by clinicians to rate the likelihood of causality in adverse drug reaction (ADR) investigations is an ADR probability scale (algorithm). One such scale was developed and tested by Naranjo and colleagues.[12] This tool provides a series of scored questions that leads an investigator to the likelihood that an ADR was caused by the suspected medication. Depending on the aggregate score, the causality is rated as *doubtful, possible, probable, or definite*. The scale gives the most weight to the temporal relationship of the reaction with relation to administration of the drug, observations following a rechallenge of the suspected medication, and alternate explanations for the ADR. As mentioned earlier, it is often unethical to rechallenge patients who experience severe hematologic toxicities. Thus, without a rechallenge it is difficult to achieve a causality rating of *definite* with such an algorithm.

In determining the likelihood that an observed reaction is caused by a particular medication, clinicians should review the medical literature for past reports supporting the observation. Using an evidence-based approach such as that proposed by Sackett,[13] the investigator assigns greater weight to prospective study designs such as clinical trials or cohort studies than to case reports or expert opinion. This will provide a framework for the investigator's confidence in published literature describing ADRs.

In this chapter, we use both methods described to review and present published information on hematologic drug toxicities. When only case reports were available, the Naranjo algorithm was applied to the cases (if not already used). *Definite* and those rated as *probable* when only a lack of rechallenge prevented a rating of *definite* were included in the lists. An evidence-based approach was incorporated through a review of the medical literature for prospective and retrospective studies of the adverse reactions and medications of interest. Drugs significantly associated with an adverse reaction of interest through studies were also deemed to have a causal relationship to the reaction.

The understanding of drug-induced hematologic disorders requires a basic understanding of hematopoiesis. The pluripotential hematopoietic stem cells in the bone marrow, which have the ability to self-reproduce, maintain the blood. These pluripotential hematopoietic stem cells further differentiate to intermediate precursor cells, which are also called *progenitor cells or colony-forming cells*. Committed to a particular cell line, these intermediate stem cells differentiate into colonies of each type of blood cell in response to specific colony-stimulating factors (Fig. 112–1).

Drug-induced hematologic disorders can affect any cell line, including white blood cells (WBCs), red blood cells (RBCs), and platelets. When a drug causes decreases in all three cell lines accompanied by a hypoplastic bone marrow, the result is drug-induced aplastic anemia. The decrease in WBC count alone by a medication is drug-induced agranulocytosis. Drugs can affect RBCs by causing a number of different anemias, including drug-induced immune hemolytic anemia, drug-induced oxidative hemolytic anemia, or drug-induced megaloblastic anemia. A drug-induced decrease in platelet count is drug-induced thrombocytopenia.

DRUG-INDUCED APLASTIC ANEMIA

Aplastic anemia is a rare, serious disease of unclear etiology. It was first described by Ehrlich in 1888 following an episode of failed hematopoiesis identified during the autopsy of a pregnant woman.[14] Since that first report, numerous cases of aplastic

anemia have been described, but the true incidence of the disease remains uncertain. Best estimates report an incidence of two to seven cases per million inhabitants.[15,16,17] Interestingly, the incidence of aplastic anemia is different in different regions, which suggests an environmental component to the etiology of this condition.[4,15,16] There is also debate regarding the peak age at which aplastic anemia is most common. Some authors have reported a peak incidence in patients younger than age 30 years while others report the highest incidence in those older than age 60 years.[4,15–18,19] When the results of all studies are considered, the young and elderly appear to be at increased risk for the development of aplastic anemia.

Aplastic anemia can be broken down into two very broad categories—inherited and acquired. Although this chapter will focus on one specific type of acquired aplastic anemia, it is important to be aware of inherited disorders of bone marrow failure because they can be misdiagnosed as acquired.[18] Inherited types of bone marrow failure typically present in the first decade of life, are often associated with physical anomalies (e.g., short stature and café-au-lait spots), and rarely respond to immunosuppressive therapies.[18] Acquired aplastic anemia accounts for the large majority of cases, and as with many other autoimmune disorders, genetic factors may predispose some patients to acquire aplastic anemia.[20,21] A number of variables can incite immune destruction of the bone marrow; the most common are drugs, insecticides, benzene and other chemical exposure, viruses, and radiation. It has been estimated that 25% to 40% of aplastic anemia cases are related to one of these external factors.[22] However, in the large majority of modern cases, a definitive causative agent cannot be identified.[18,23]

Aplastic anemia is characterized by pancytopenia (presence of anemia, neutropenia, and thrombocytopenia) with a hypocellular bone marrow and no gross evidence of increased peripheral blood cell destruction.[24] A diagnosis of aplastic anemia can be made by the presence of two of the following criteria: a WBC count of 3,500 cells/mm^3 (3.5×10^9/L) or less, a platelet count of 55,000 cells/mm^3 (55×10^9/L) or less, or a hemoglobin value of 10 g/dL (100 g/L; 6.21 mmol/L) or less with a reticulocyte count of 30,000 cells/mm^3 (30×10^9/L) or less.[25] However, all of these blood counts do not decrease at the same rate.

Once diagnosed, acquired aplastic anemia can be classified as nonsevere, severe, or very severe based on the degree of bone marrow cellularity and peripheral neutrophil, platelet, and reticulocyte counts. Severe aplastic anemia is defined by at least two of the following three peripheral blood findings: neutrophil count of less than 500 cells/mm^3 (500×10^6/L), platelet count of less than 20,000 cells/mm^3 (20×10^9/L), and anemia with a corrected reticulocyte index of less than 1%.[26,27] The prognosis is poor if the neutrophil count declines to less than 200 cells/mm^3 (200×10^6/L), which is the definition of very severe.[28,29] A bone marrow aspirate and biopsy are required to exclude other causes of pancytopenia.[30] There must also be no history of iatrogenic exposure to cytotoxic chemotherapy that is known to cause transient bone marrow suppression or to intensive radiation.

Aplastic anemia is considered the most serious drug-induced blood dyscrasia because of the associated high mortality rate as compared with other blood dyscrasias.[26,31] The onset of drug-induced aplastic anemia is variable and insidious. Symptoms have been reported to appear from days to months after initiation of the offending drug, with the average being approximately 6.5 weeks.[29] In some instances, symptoms appear after the drug has been discontinued. Neutropenia typically presents first, followed by thrombocytopenia, and finally, because of the longer life span of the RBCs, anemia evolves slowly.[32] Clinical features of drug-induced aplastic anemia depend on the degree to which each cell line is suppressed, similar to idiopathic disease. Symptoms of anemia include pallor, fatigue, and weakness, whereas fever, chills, pharyngitis, or other signs of infection can characterize neutropenia. Thrombocytopenia, often the initial clue to diagnosis, is manifest by easy bruisability, petechiae, and bleeding.

5 The cause of drug-induced aplastic anemia is damage to the pluripotential hematopoietic stem cells before their differentiation to committed stem cells. This damage effectively reduces the normal levels of circulating erythrocytes, neutrophils, and platelets. Three mechanisms have been proposed as causes of damage to the pluripotent hematopoietic stem cells.[28] The first is direct, dose-dependent drug toxicity. This type of injury leads to transient marrow failure secondary to direct suppression of proliferating cell lines, and hematopoietic suppression continues with dose escalation. Most often caused by chemotherapy or radiotherapy, this injury is frequently iatrogenic. The second mechanism is idiosyncratic and may operate through toxic metabolites of the parent drug. Furthermore, individual variations in the pharmacokinetics of the suspected drug, genetic polymorphisms altering metabolism, or a hypersensitivity of the stem cells to the destructive effects of the implicated drug may increase the potential for toxicity. The third mechanism is a drug- or metabolite-induced immune reaction specific to the stem-cell population, and it is this mechanism that has received much attention over the past few decades. Currently, it is believed that most cases of aplastic anemia are immune mediated.[17] It is proposed that exposure to an inciting antigen (drug) activates cells and cytokines of the immune system, leading to the death of stem cells.[28] Table 112–1 lists drugs that have been associated with drug-induced aplastic anemia.

The antineoplastic agents exemplify the dose-dependent mechanism for the development of aplastic anemia. Many of these agents have the ability to suppress one or more cell lines in a reversible manner. The degree of suppression and the cell line involved depend on the nature of the particular drug and its potential for inhibiting marrow proliferation. Chloramphenicol, an antimicrobial agent, also causes a bone marrow depression that is dose dependent and reversible.[33]

Idiosyncratic drug-induced aplastic anemia secondary to direct toxicity can be characterized by dose independence, a latent period prior to the onset of anemia, and continued marrow injury following drug discontinuation.[34] Chloramphenicol, already known to cause a dose-dependent reaction, is the prototype drug for the idiosyncratic mechanism. The estimated incidence of chloramphenicol-induced aplastic anemia is 1 case per 20,000 patients treated,[29] but the overall prevalence has fallen with decreased use of this agent.[34] The idiosyncratic mechanism is believed to result from abnormal metabolism of chloramphenicol. The nitrobenzene ring on chloramphenicol is thought to be reduced to form a nitroso group on the chloramphenicol molecule.[33] The nitroso group may then interact with DNA in the stem cell, causing damage to the chromosomes, and eventually cell death. Other investigators have hypothesized that bacteria from the gastrointestinal tract may metabolize chloramphenicol to marrow-toxic metabolites.[35] The dose-dependent and idiosyncratic reactions seen with chloramphenicol do not appear to be related.

Other drugs thought to induce aplastic anemia through toxic metabolites include phenytoin and carbamazepine. Investigators have theorized that metabolites of phenytoin and carbamazepine bind covalently to macromolecules in the cell and then cause cell death either by exerting a direct toxic effect on the stem cell or by causing the death of lymphocytes involved in regulating hematopoiesis.[36]

Of the three potential mechanisms, the most common cause of drug-induced aplastic anemia is the development of an immune reaction. Early laboratory studies showed that removal of T lymphocytes from patients with aplastic anemia improved in vitro colony formation.[37] Furthermore, overproduction of cytokines

Ticlopidine

NSAID, nonsteroidal antiinflammatory drug.

(e.g., tumor necrosis factor and interferon-γ) from activated T lymphocytes appears to be responsible for hematopoietic failure, as well as for the initiation of apoptosis.[17,38] The observation of improved hematopoiesis in aplastic anemia patients who receive a conditioning regimen with antithymocyte globulin and cyclophosphamide prior to allogeneic hematopoietic stem cell transplantation (HSCT) supports this hypothesis.[39] After the initiation of immunosuppressive therapy, bone marrow concentrations of interferon-γ decreased, whereas all cell lines improved.[40]

Additional support for an immunologic basis as a mechanism of aplastic anemia comes from a prospective, randomized, placebo-controlled trial evaluating the efficacy of antilymphocyte globulin and methylprednisolone, with or without cyclosporine, in patients with severe aplastic anemia.[41] The primary response variable was an improvement in blood counts (i.e., platelets, erythrocytes, and leukocytes) at 3 months. Patients receiving therapy with antilymphocyte globulin, methylprednisolone, and cyclosporine had a response rate of 65% versus a response rate of 39% in the group not receiving cyclosporine. The favorable response rate with immunosuppressant drugs supports the overall hypothesis of an immune-based mechanism for aplastic anemia. One can also conclude that the degree of immunosuppression is related to a better response rate.

Genetic predisposition can also influence the development of drug-induced aplastic anemia. Studies in animals and a case report of chloramphenicol-induced aplastic anemia in identical twins suggest a genetic predisposition to the development of drug-induced aplastic anemia.[29,33] Furthermore, pharmacogenetic research that focuses on patients who may be slow or normal metabolizers of drugs can increase the clinician's ability to predict the development of aplastic anemia. Initial case-control studies have not had the statistical power necessary to identify a significant difference between controls and cases, but continued research may establish the role of altered metabolism in patients with aplastic anemia.[42]

TREATMENT

Drug-Induced Aplastic Anemia

Because of the high mortality rate associated with severe and very severe aplastic anemia, it is imperative that drug-induced aplastic anemia be diagnosed quickly and therapy initiated immediately. Treatment should be based on the degree of cytopenia, and the goals of therapy are to improve peripheral blood counts, which limits the requirement for transfusions and minimizes the risk for opportunistic infections.

6 As with all cases of drug-induced hematologic disorders, the first step is to remove the suspected offending agent. Early withdrawal of the drug can allow for reversal of the aplastic anemia.[29] The next step is to provide adequate supportive care, including appropriate antimicrobial therapy for the treatment of infection and transfusion support with erythrocytes and platelets. The routine use of recombinant human erythropoietin has been shown to be ineffective and is not recommended for the management of aplastic anemia. Appropriate supportive care is essential because the major causes of mortality in patients with aplastic anemia are bacterial or fungal infections and bleeding. Current treatment guidelines for aplastic anemia recommend the use of prophylactic antibiotic and antifungal agents when neutrophil counts are below 200 cells/mm^3 (200 $\times$ 10^6/L), but do not recommend prophylaxis for *Pneumocystis jirovecii* or use of antivirals unless the patient has undergone an HSCT. Therefore, fever of unknown origin should be initially managed with broad-spectrum antibiotics and not with agents that were used for prophylaxis. The use of granulocyte colony-stimulating factor (G-CSF) may be considered in patients not responding to antimicrobial therapy, but these agents should be discontinued after 1 week if there is no increase in neutrophil count.[30]

The clinical course of aplastic anemia is variable. The condition can progress to severe or very severe disease in some patients, although it can remain relatively stable or even resolve in others.[17] The treatment of moderate disease ranges from no clinical intervention to immunosuppressive regimens, and treatment should be based on the degree of cytopenias.[17,18]

For patients with disease requiring treatment, the two major treatment options for patients with drug-induced aplastic anemia are allogeneic HSCT and immunosuppressive therapy. Most experts consider allogeneic HSCT the treatment of choice for young patients who have human leukocyte antigen (HLA)-matched sibling donors.[30] Most patients are cured after HSCT, and the 5-year survival of patients following a matched sibling donor transplant has been reported to be 77% for adults and up to 80% to 90% in children.[17,43] Despite these promising results, relatively few patients are eligible for HSCT because less than 30% of patients have a matched sibling donor.[44] For those patients who do not have a matched sibling donor, mismatched related and matched unrelated donor transplants may be an option, but the prognosis is less optimistic. A recent published review of unrelated donor stem cell transplantation in severe aplastic anemia reported a 5-year overall survival rate ranging between 28% and 94% from eight studies.[44] The highest mortality rate was seen in older patients and those with poorer clinical status at the

time of transplantation. Complications for HSCT, such as graft-versus-host disease (GVHD) and graft rejection, require all patients to be closely monitored for an extended period of time.

An alternative to allogeneic HSCT is immunosuppressive therapy, which tends to be first-line therapy for older patients and those who are not candidates for HSCT. The current standard regimen against which new therapies are measured is combination therapy with antithymocyte globulin (ATG) and cyclosporine.[45] This combination has been reported to achieve 5-year survival rates between 75% and 85%, but the response rates in older patients are lower.[44] ATG is composed of polyclonal immunoglobulin G (IgG) against human T-lymphocytes derived from either horses or rabbits, and it has been a standard component of immunosuppressive therapy for aplastic anemia for many years. Most of the studies used horse-derived ATG, and one recent trial reported a lower response rate in patients whose regimen contained rabbit-derived ATG versus those who received horse-derived ATG.[47] However, rabbit-derived ATG can produce satisfactory responses in patients who had failed previous treatment with horse-derived ATG.[46] More data are needed to determine the role of rabbit-derived ATG in the treatment of aplastic anemia. Since response to immunosuppressive therapy is often delayed (3–4 months), patients will need to continue supportive care until recovery. Patients will require monitoring for adverse effects, including serum sickness, which can occur approximately 1 week after ATG begins.[44]

Cyclosporine plays a key role in immunosuppressant therapy for aplastic anemia. Although cyclosporine monotherapy has been used in moderate cases of aplastic anemia, it is more often used in combination with ATG. The addition of cyclosporine to ATG therapy has been shown to increase response rate, improve failure-free survival, and reduce the number of immunosuppressive courses needed.[45,47] Cyclosporine inhibits interleukin-2 production and release and subsequent activation of resting T cells. Cyclosporine dosing has varied from 4 to 6 mg/kg per day to 10 to 12 mg/kg per day, with the most frequently reported initial dose of 5 mg/kg per day in two divided doses. Cyclosporine doses are titrated to a target blood concentration that can be patient and institution specific but is usually in the range of 150 to 250 mcg/L (125 to 208 nmol/L) for adult patients. Increased rates of relapse have been seen when tapering cyclosporine rapidly, and it is recommended that cyclosporine be continued for at least 12 months after response and then tapered slowly.[44] Corticosteroids are added to ATG-based immunosuppression due to their ability to reduce adverse reactions associated with ATG administration. In an effort to improve outcomes, several other agents have also been investigated in the treatment of aplastic anemia. The additive benefits of other immunosuppressive agents such as mycophenolate, cyclophosphamide, and sirolimus have been evaluated.[17] However, they have not been shown to be superior to the combination of ATG and cyclosporine, and their place in therapy is not defined.[48]

CLINICAL CONTROVERSY

Allogeneic HSCT has long been the established treatment of drug-induced aplastic anemia. More recently, immunosuppressive regimens combining antithymocyte globulin, glucocorticoids, and cyclosporine are gaining favor. The usefulness of each treatment modality is limited by various factors. Clinical data suggest that there is no difference in survival achieved with the two treatments among patients followed for 6 years. Parity between the treatments will necessitate that clinicians individualize treatment decisions, while considering risk factors, economics, and quality of life.

DRUG-INDUCED AGRANULOCYTOSIS

Agranulocytosis is defined as a reduction in the number of mature myeloid cells in the blood (granulocytes and immature granulocytes [bands]) to a total count of 500 cells/mm^3 (500 × 10^6/L) or less. It occurs most commonly in females and the elderly (i.e., >60 years of age),[49] with an estimated annual incidence of 1.1 to 12 cases per million population.[16,50] However, a multinational case-control study in Latin American countries demonstrated a much lower rate of 0.38 cases per million inhabitant-years.[3] The overall mortality rate of agranulocytosis is estimated to be 3.5% to 16%, and that rate is highest among the elderly and patients with renal failure, bacteremia, or shock at the time of diagnosis.[16,50] Of those cases reported since 1990, approximately 5% to 6% have resulted in fatal outcomes.[51] Symptoms of agranulocytosis include sore throat, fever, malaise, weakness, chills, and other signs and symptoms of infection. These symptoms can appear rapidly, within days to weeks after the initiation of the offending drug. The median duration of exposure prior to the development of agranulocytosis ranges from 19 to 60 days for most drugs associated with this adverse event, but the time to onset is greater than 1 month for most of these agents.[51] Drug-induced agranulocytosis will usually resolve over time with supportive care and management of infection. Time to neutrophil recovery has typically been reported to range from 4 to 24 days.[51] Table 112–2 provides a list of medications that have been associated with drug-induced agranulocytosis.

The cause of drug-induced agranulocytosis is not fully understood, and several mechanisms have been proposed. Initially, it was thought that drugs affected only the mature granulocytes, causing a *maturation arrest*. However, more recent studies have demonstrated that drugs may have either a direct toxic effect or an antibody-mediated effect on the bone marrow, neutrophils, or stem cells. Several immune-mediated mechanisms have been proposed.[49]

The first type of immune-mediated mechanism involves the drug or drug metabolite, antibodies, and neutrophils. This mechanism involves drug adsorption on the membrane of the neutrophil. The drug-membrane complex then acts as a hapten to stimulate antibody formation. The antibodies produced bind to the drug–membrane complex, causing WBC destruction through complement activation and removal by the phagocytic system (Fig. 112–2). This hapten-type reaction is often seen when drugs, such as the penicillin derivatives, are given in large doses. Continuous presence of the drug is required for the destruction of neutrophils in this type of reaction.

The second mechanism of immune-mediated agranulocytosis is called the *innocent bystander phenomenon*. In this reaction, the drug combines with a drug-specific antibody. The complex is nonspecifically adsorbed to the neutrophil membrane, resulting in complement activation. The activated complement then destroys the cell (Fig. 112–3). Quinidine has been associated with this type of reaction. Functioning in a manner somewhat similar to that of the second mechanism, the third mechanism of immune response involves a protein carrier that combines with the drug and then attaches to the cell membrane. This in turn causes antibody formation. The antibodies bind to the drug protein carrier–membrane complex and activate complement. The cells are then cleared by the phagocytic system (Fig. 112–4).

In addition, there are several other immune-mediated mechanisms that have been identified. The production of autoantibodies to a *spoiled membrane* is a mechanism in which the offending drug alters the neutrophil membrane. This alteration induces the formation of autoantibodies (antibodies that attach directly to the neutrophil), which causes cellular destruction by the phagocytic system. High concentrations of β-lactam antibiotics, carbamazepine, and valproic acid have been associated with inhibition of colony-forming units of granulocytes and macrophages.

TABLE 112-2 Drugs Associated with Agranulocytosis

Observational Study Evidence	Case Report Evidence (*Probable* or *Definite* Causality Rating)	
β-Lactam antibiotics	Acetaminophen	Levodopa
Carbamazepine	Acetazolamide	Meprobamate
Carbimazole	Ampicillin	Methazolamide
Clomipramine	Captopril	Methyldopa
Digoxin	Carbenicillin	Metronidazole
Dipyridamole	Cefotaxime	Nafcillin
Ganciclovir	Cefuroxime	NSAIDs
Glyburide	Chloramphenicol	Olanzapine
Gold salts	Chlorpromazine	Oxacillin
Imipenem-cilastatin	Chlorpropamide	Penicillamine
Indomethacin	Chlorpheniramine	Penicillin G
Macrolide antibiotics	Clindamycin	Pentazocine
Methimazole	Clozapine	Phenytoin
Mirtazapine	Colchicine	Primidone
Phenobarbital	Doxepin	Procainamide
Phenothiazines	Dapsone	Propylthiouracil
Prednisone	Desipramine	Pyrimethamine
Propranolol	Ethacrynic acid	Quinidine
Spironolactone	Ethosuximide	Quinine
Sulfonamides	Flucytosine	Rifampin
Sulfonylureas	Gentamicin	Streptomycin
Ticlopidine	Griseofulvin	Terbinafine
Valproic acid	Hydralazine	Ticarcillin
Zidovudine	Hydroxychloroquine	Tocainide
	Imipenem-cilastatin	Tolbutamide
	Imipramine	Vancomycin
	Lamotrigine	

NSAID, nonsteroidal antiinflammatory drug.

Finally, drug-induced apoptosis and direct toxicity for pluripotent or bipotent hematopoietic progenitor stem cells have also been associated with clozapine and ticlopidine, respectively.[49]

In the case of penicillin-induced agranulocytosis, the patient can often begin taking penicillin again, at a lower dosage, after the neutropenia has resolved without any relapse of drug-induced agranulocytosis.[52] Because of the rapid onset of symptoms and the dose-related phenomenon, a second mechanism could possibly be involved with penicillin-induced agranulocytosis. That mechanism involves an accumulation of drug to toxic concentrations in hypersensitive individuals. Researchers have shown with in vitro cell cultures that penicillin derivatives in high concentrations inhibit the growth of myeloid colony-forming units in patients recovering from drug-induced agranulocytosis.[53] Penicillin derivatives, therefore, may suppress WBCs by several mechanisms.

Antithyroid medications, such as propylthiouracil and methimazole, have been reported to cause agranulocytosis. The current incidence of this adverse effect is unknown, but early publications report agranulocytosis in approximately 0.3% to 0.6% of patients.[54] In two more recent reports, antithyroid medications accounted for 7% to 23% of drug-induced agranulocytosis cases investigated.[55,56] The mechanism by which antithyroid agents cause agranulocytosis is unknown, but antineutrophil cytoplasmic antibodies have been identified.[57] In a study by Cooper and coworkers, agranulocytosis occurred more frequently in older patients (>40 years old) and appeared within 2 months after the initiation of therapy; a possible dose-response relationship was also observed.[54] More recently Takata and colleagues found the prevalence of neutropenia to be significantly greater in patients receiving methimazole 30 mg daily compared with those receiving 15 mg per day.[58] No dose-response

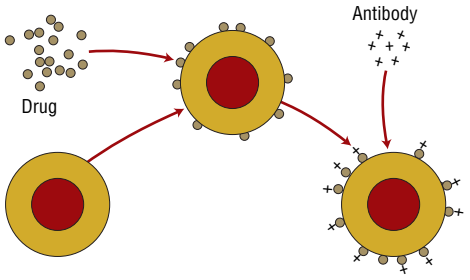

FIGURE 112-2. Drug adsorption mechanism. The drug binds to the membrane of the blood cell. Antibodies are formed to the drug–membrane complex (hapten). The antibodies then attach to the complex, and cell toxicity occurs. *(This article was published in Transfus Med Rev, Vol 7(Oct), Petz LD, Drug-induced autoimmune hemolytic anaemia, pages 242–254, Copyright © Elsevier 1993.)*

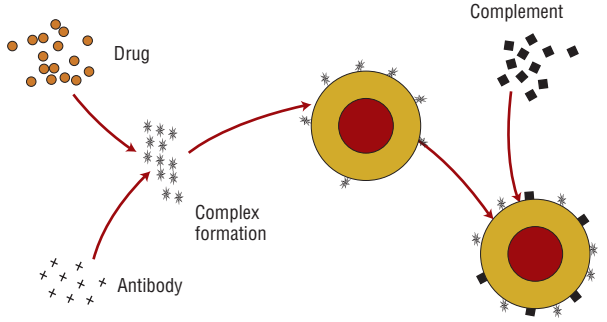

FIGURE 112-3. Innocent bystander mechanism. The drug induces antibody formation. The antibodies and drug form a complex in the serum, and the complex nonspecifically binds to the cell membrane. Complement is activated, and the cell is lysed. *(This article was published in Ballieres Clin Haematol, Vol 91, Petz LD, Drug-induced haemolytic anaemia, pages 455–482, Copyright © Elsevier 1980.)*

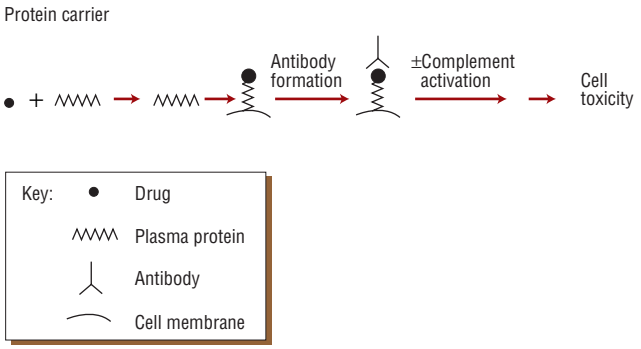

FIGURE 112-4. Protein carrier mechanism. The drug combines with a plasma protein. The complex then attaches to the cell membrane, and antibody formation is stimulated. Antibodies later attach to the complex and activate complement. The cell is then lysed by the complement. *(This article was published in Clin Haematol, Vol 9(Oct), Young GA, Vincent PC, Drug-induced agranulocytosis, pages 483–504, Copyright © Elsevier 1980.)*

relationship has been observed with conventional doses of propylthiouracil. However, another study demonstrated no relationship between age or dose and the incidence of thionamide-induced agranulocytosis.[59]

Ticlopidine is an antiplatelet agent indicated for the treatment of cerebrovascular disease and the prevention of reocclusion associated with stent placement. It produces neutropenia in approximately 2.4% of patients and agranulocytosis in 0.8%,[60] possibly by inhibiting hematopoietic progenitor stem cells.[49] Patient factors that can be associated with the development of agranulocytosis include poor bone marrow reserve and age. Agranulocytosis most commonly occurs within 1 to 3 months from the initiation of ticlopidine. Removal of the drug is the best treatment option, with counts usually returning to normal within 2 to 4 weeks. The phenothiazine class of drugs is known to cause drug-induced agranulocytosis by the innocent bystander mechanism. The onset of phenothiazine-induced agranulocytosis is approximately 2 to 15 weeks after the initiation of therapy, with a peak onset between 3 and 4 weeks.[61,62] The mechanism by which phenothiazines cause drug-induced agranulocytosis has been studied primarily with chlorpromazine,[63] which is thought to affect cells in the cell cycle phase that manufactures enzymes needed for DNA synthesis (G_1 phase), or the phase in which cells are resting and not committed to cell division (G_0 phase).[63] The antipsychotic agents are known to precipitate proteins and may co-precipitate polynucleotides so they can no longer participate in nucleic acid synthesis. Chlorpromazine also increases the loss of macromolecules from the intracellular pools that are essential for cellular replication.[63] When the bone marrow from a patient with phenothiazine-induced agranulocytosis is examined, it initially appears to have no cellularity (aplastic), but over time it becomes hyperplastic. It is believed that toxic effects of the phenothiazines are not seen in all patients taking the medications because most patients have enough bone marrow reserve to overcome the toxic effects.[63]

Clozapine, an antipsychotic agent, is associated with a significantly higher risk of agranulocytosis as compared with other antipsychotic medications and has received much attention over recent years.[64] The annual incidence of clozapine-induced agranulocytosis in the United States is reported to be 1.3% and can occur at any time during treatment, although the risk is highest at around 3 months after initiation.[65] Because of the frequency and seriousness of clozapine-induced agranulocytosis and because of its reversible nature if detected early in therapy, clozapine is currently only available through a limited distribution program that requires strict WBC count monitoring.[65] In vitro studies have suggested that the formation of a nitrenium ion unstable metabolite may be responsible for clozapine-induced agranulocytosis.[49] The resulting oxidative stress caused by this metabolite may cause cytotoxicity or an immune reaction.[66]

TREATMENT

Drug-Induced Agranulocytosis

The primary treatment of drug-induced agranulocytosis is the removal of the offending drug. Following discontinuation of the drug, most cases of neutropenia resolve over time, and only symptomatic treatment (e.g., antimicrobials for infections) and appropriate vigilant hygiene practices are necessary. Sargramostim (GM-CSF) and filgrastim (G-CSF) have been shown to shorten the duration of neutropenia, length of antibiotic therapy, and hospital length of stay.[50] Although the use of both agents has been reported in the literature, a commonly reported regimen is G-CSF 300 mcg/day via subcutaneous injection. The only prospective, randomized trial to date did not confirm the benefit of these growth factors.[67] However, some experts have questioned the validity of these results based on the small sample size ($n = 24$) and the lower than standard dose of filgrastim used (i.e., 100–200 mcg/day). One systematic review found that patients with a neutrophil nadir less than 100 cells/mm^3 (100×10^6/L) had a higher rate of infections and fatal complications as compared to those with a higher nadir.[51] Therefore, some clinicians recommend the use of growth factors in patients with a neutrophil nadir less than 100 cells/mm^3 (100×10^6/L), regardless of the presence of infection.

DRUG-INDUCED HEMOLYTIC ANEMIA

Following their release from the bone marrow, normal RBCs survive for approximately 120 days before they are removed by phagocytic cells of the spleen and liver. The process of premature RBC destruction is referred to as hemolysis, which can occur because of either defective RBCs or abnormal changes in the intravascular environment. Drugs can promote hemolysis by both processes.

The causes of drug-induced hemolytic anemia can be divided into two categories: immune or metabolic. Those in the first category may operate much like the process that leads to immune-mediated agranulocytosis, or they can suppress regulator cells, which can lead to the production of autoantibodies. The second category involves the induction of hemolysis by metabolic abnormalities in the RBCs. Patients with drug-induced hemolytic anemia can present with signs of intravascular or extravascular hemolysis. Intravascular hemolysis, the lysis of RBCs in the circulation, can result from trauma, complement fixation to the RBC, or exogenous toxic factors. Extravascular hemolysis refers to the ingestion of RBCs by macrophages in the spleen and liver, a process that requires the presence of surface abnormalities on RBCs, such as bound immunoglobulin.[68]

The onset of drug-induced hemolytic anemia is variable and depends on the drug and mechanism of the hemolysis. Symptoms of hemolytic anemia can include fatigue, malaise, pallor, and shortness of breath. Table 112–3 provides a list of drugs that have been associated with drug-induced immune hemolytic anemia.

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

In immune hemolytic anemia, IgG and/or immunoglobulin M (IgM) bind to antigens on the surface of RBCs and initiate their destruction through the complement and mononuclear phagocytic systems.[69]

Triamterene

NSAID, nonsteroidal antiinflammatory drug.

Depending on the antigenic stimulus, immune hemolytic anemia is either classified as autoimmune, alloimmune, or drug-induced.[69] Drug-induced antibodies may recognize the host's intrinsic RBC antigens or RBCs bound to drug. If the antibodies react against RBC-bound drug, then the drug must be present to induce hemolysis.[69]

A laboratory test called the direct Coombs test (or direct antiglobulin test [DAT]), which identifies foreign immunoglobulins either in the patient's serum or on the RBCs themselves, is the best means to diagnose drug-induced immune hemolytic anemia. The Coombs test begins with the antiglobulin serum, which is produced by injecting rabbits with preparations of human complement, crystallizable fragment (of immunoglobulin) (Fc), or immunoglobulins. The rabbits produce antibodies against human immunoglobulins and complement. The direct Coombs test involves combining the patient's RBCs with the antiglobulin serum. If the patient's RBCs are coated with antibody or complement (as a result of a drug-induced process), the antibodies in the serum (produced by the rabbit) will attach to the Fc regions of the autoimmune globulins on separate RBCs, creating a lattice formation called agglutination.[70] This agglutination is considered positive for the presence of IgG or complement on the cell surfaces.

An indirect Coombs test can identify antibodies in a patient's serum. This test is performed by combining the patient's serum with normal RBCs, then subjecting them to the direct Coombs test. Antibodies that have attached to the normal RBCs will be identified. This process is important in blood bank procedures.

The mechanisms that have been proposed to explain how drugs can induce immune hemolytic anemia are similar to the mechanisms that produce drug-induced agranulocytosis. The first mechanism is the adsorption of the drug to the RBC membrane to form a hapten, and subsequently, an antibody. The antibody attaches to the drug without direct interaction with the erythrocyte. The extravascular anemia that follows is usually caused by IgG, and generally complement is not activated. The anemia usually develops gradually over 7 to 10 days and reverses over a couple of weeks after the offending drug is discontinued. The direct Coombs test may remain positive for several weeks. The penicillin and cephalosporin derivatives given in high doses are primarily associated with this type of immune reaction.[71] Other drugs that have been reported to cause drug-induced immune hemolytic anemia by this process include minocycline, tolbutamide, and semisynthetic penicillins.[71] Streptomycin is also associated with this type of reaction and is associated with activation of the complement system.[72]

Like drug-induced agranulocytosis, immune hemolytic anemia has been associated with the formation of immune complexes in a reaction formally known as the *innocent bystander phenomenon*. Quinidine and phenacetin are the prototype drugs of this reaction, but many other drugs have been implicated, including quinine and several sulfonamides. Drugs that induce this reaction bind weakly to a normal RBC component. The immune system identifies this complex as foreign, a *neoantigen*, and initiates lysis of the RBC via the complement system.[69] As soon as complement is activated, the complex can detach and move on to other RBCs, and to WBCs or platelets. Because of this low affinity, only a small amount of drug is needed to cause the reaction, and the direct Coombs test is positive for complement only. RBCs are essentially victims, or "innocent bystanders," of the immunologic reaction. This type of mechanism is associated with acute intravascular hemolysis that can be severe, sometimes leading to hemoglobinuria and renal failure. Following discontinuation and clearance of the drug from the circulation, the direct Coombs test will become negative.

The third mechanism is drug-induced autoimmune hemolytic anemia. The first drug implicated in this type of hemolytic anemia was methyldopa.[73] Like some other drugs, methyldopa is known to induce true autoantibodies to RBCs; the antibodies can be identified without the presence of the offending drug or its metabolites. Approximately 10% to 20% of patients receiving methyldopa will develop a positive Coombs test, usually within 6 to 12 months of initiating therapy.[74] However, less than 1% of these patients experience hemolysis, and hemolysis can develop from 4 to 6 months to more than 2 years after the start of therapy. After the withdrawal of the drug, results of the Coombs test can remain positive for many months.[72] The mechanism by which methyldopa induces antibody production is not completely known, but there are two main hypotheses.[73] The first suggests that methyldopa or its metabolites acts on the immune system and impairs immune tolerance. An alternative hypothesis suggests that the offending drug may bind to immature RBCs, altering the membrane antigens and inducing autoantibodies.

The fourth and newest mechanism that has been suggested is that of nonimmune protein adsorption (NIPA). With this mechanism, the drug alters the RBC membrane such that normal plasma proteins, including IgG, become adsorbed to the RBC membrane. RBCs coated with IgG then interact with macrophages, thereby resulting in hemolysis.[75,76]

It is not known why only some patients develop autoantibodies, and why only some of the patients who have autoantibodies develop

hemolytic disease. In an effort to explain why patients have a positive result from a Coombs test and no hemolysis, Kelton demonstrated that methyldopa impairs the ability of these patients to remove antibody-sensitized cells.[77] In Coombs-positive patients receiving methyldopa, patients with impairment of the mononuclear phagocytic system could not clear the RBCs coated with autoantibodies from their bloodstream, and therefore hemolysis did not occur. Patients with hemolysis had no impairment of the mononuclear phagocytic system. Procainamide has also been reported to cause a positive result on the indirect Coombs test and hemolytic anemia.[78] Other drugs that have been reported to cause autoimmune hemolytic anemia include levodopa, mefenamic acid, and diclofenac.[79]

DRUG-INDUCED OXIDATIVE HEMOLYTIC ANEMIA

A hereditary condition, drug-induced oxidative hemolytic anemia, most often accompanies a glucose-6-phosphate dehydrogenase (G6PD) enzyme deficiency, but it can occur because of other enzyme defects (reduced nicotinamide adenine dinucleotide phosphate [NADPH] methemoglobin reductase or reduced glutathione peroxidase). A G6PD deficiency is a disorder of the hexose monophosphate shunt, which is responsible for producing NADPH in RBCs, which in turn keeps glutathione in a reduced state. Reduced glutathione is a substrate for glutathione peroxidase, an enzyme that removes peroxide from RBCs, thus protecting them from oxidative stress.[80] Without reduced glutathione, oxidative drugs can oxidize the sulfhydryl groups of hemoglobin, removing them prematurely from the circulation (i.e., causing hemolysis).

A G6PD deficiency is the most common of all enzyme defects, affecting millions of people. Because the G6PD gene is located on the X chromosome, the disorder is therefore inherited through a sex-linked mode. Both homozygotes and heterozygotes can be symptomatic, but homozygotes tend to have the most severe cases.[81] There are many G6PD variants, but the most common types occur in American and African blacks (approximately 10%), people from Mediterranean areas (e.g., Greeks, Sardinians, and Khurdic and Sephardic Jews), and Asians.[81]

The degree of hemolysis depends on the severity of the enzyme deficiency and the amount of oxidative stress. However, the dose required for hemolysis to occur is often less than prescribed quantities of the suspected drug.[72,80] Although severe hemolysis is rare, any drug that places oxidative stress on RBCs can cause drug-induced oxidative hemolytic anemia. One case of drug-induced oxidative hemolytic anemia has been reported in a child when dapsone (an oxidizing agent) was transferred through the breast milk of the mother, who was taking the drug.[82] For a list of agents associated with drug-induced oxidative hemolytic anemia, refer to Table 112–4.

TREATMENT

Drug-Induced Hemolytic Anemia

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

The severity of drug-induced immune hemolytic anemia depends on the rate of hemolysis. Hemolytic anemia caused by drugs through the hapten/adsorption and autoimmune mechanisms tends to be slower in onset and mild to moderate in severity. Conversely, hemolysis prompted through the neoantigen mechanism (innocent bystander) phenomenon can have a sudden onset, lead to severe hemolysis, and result in renal failure. The treatment of drug-induced immune hemolytic anemia includes the removal of the offending agent and supportive care. In severe cases, glucocorticoids can be helpful,[69] but some practitioners have questioned their efficacy.[79] Other agents such as the chimeric anti-CD20 monoclonal antibody rituximab and immunoglobulin treatments have been used, but their role is yet to be clearly defined.[83,84]

DRUG-INDUCED OXIDATIVE HEMOLYTIC ANEMIA

Removal of the offending drug is the primary treatment for drug-induced oxidative hemolytic anemia. No other therapy is usually necessary, as most cases of drug-induced oxidative hemolytic anemia are mild in severity. Patients with these enzyme deficiencies should be advised to avoid medications capable of inducing the hemolysis.

DRUG-INDUCED MEGALOBLASTIC ANEMIA

In drug-induced megaloblastic anemia, the development of RBC precursors called megaloblasts in the bone marrow is abnormal.

Deficiencies in either vitamin B_{12} or folate are responsible for the impaired proliferation and maturation of hematopoietic cells, resulting in cell arrest and subsequent sequestration. Examination of peripheral blood shows an increase in the mean corpuscular hemoglobin concentration. These megaloblastic changes are caused by the direct or indirect effects of the drug on DNA synthesis. Some patients can have a normal-appearing cell line, and the diagnosis must be made by measurement of vitamin B_{12} and folate concentrations. The abnormality can be seen in any portion of the replication process, including DNA assembly, base precursor metabolism, or RNA synthesis.[85]

Because of their pharmacologic action on DNA replication, the antimetabolite class of chemotherapeutic agents is most frequently associated with drug-induced megaloblastic anemia. Methotrexate, an irreversible inhibitor of dihydrofolate reductase, causes megaloblastic anemia in 3% to 9% of patients.[86] Dihydrofolate reductase is an enzyme responsible for generating tetrahydrofolate, an essential factor in making deoxythymidine triphosphate, which is necessary for DNA synthesis. Other drugs such as cotrimoxazole, phenytoin, or the barbiturates have also been implicated in megaloblastic anemia. Cotrimoxazole, for example, has been reported to cause drug-induced megaloblastic anemia with both low and high doses,[87,88] particularly in patients with a partial vitamin B_{12} or folate deficiency.[85] Because the drug's affinity for human dihydrofolate reductase is low, patients with adequate stores of these vitamins are at low risk of developing drug-induced megaloblastic anemia. It has been postulated that phenytoin, primidone, and phenobarbital cause drug-induced megaloblastic anemia by either inhibiting folate absorption or by increasing folate catabolism. In both instances,

the patient develops a relative deficiency of folate. Table 112–5 provides a list of drugs that have been suggested as causative factors in drug-induced megaloblastic anemia.

TREATMENT

Drug-Induced Megaloblastic Anemia

When drug-induced megaloblastic anemia is related to chemotherapy, no real therapeutic option is available, and the anemia becomes an accepted side effect of therapy. If drug-induced megaloblastic anemia results from cotrimoxazole, a trial course of folinic acid, 5 to 10 mg up to four times a day, can correct the anemia.[87,88] Folic acid supplementation of 1 mg every day often corrects the drug-induced megaloblastic anemia produced by either phenytoin or phenobarbital, but some clinicians suggest that folic acid supplementation can decrease the effectiveness of the antiepileptic medications.[89]

DRUG-INDUCED THROMBOCYTOPENIA

Thrombocytopenia is usually defined as a platelet count below 100,000 cells/mm^3 (100×10^9/L) or >50% reduction from baseline values. Thrombocytopenia can be caused by numerous conditions such as blood loss, infection, diffuse intravascular coagulation, and the use of some medications. The annual incidence of drug-induced thrombocytopenia is approximately 10 cases per 1,000,000 population (excluding those cases associated with heparin).[90] Although numerous epidemiologic studies have been reported, none of them have identified patient-specific risk factors that are associated with an increased risk for the development of drug-induced thrombocytopenia.[90]

Drug-induced thrombocytopenia can result from immune-mediated mechanisms or through a nonimmune-mediated mechanism. Nonimmune-mediated mechanisms, such as direct-toxicity-type reactions, are associated with medications that cause bone marrow suppression. This results in suppressed thrombopoiesis and a decreased number of megakaryocytes. This type of reaction is commonly associated with chemotherapeutic agents. Several mechanisms have been proposed for the development of immune-mediated drug-induced thrombocytopenia: hapten-type immune reactions, drug-dependent antibodies, fiban-induced thrombocytopenia, drug-specific antibodies, autoantibody induction, and immune complex thrombocytopenia (heparin-induced thrombocytopenia).[91] While direct toxicity reactions result in decreased megakaryocytes, in contrast, immune reactions result in an increased peripheral destruction of platelets and an increased number of megakaryocytes. The clinical consequences of thrombocytopenia associated with each one of these mechanisms except the immune complex mechanism is hemorrhage. In contrast, immune complex thrombocytopenia or HIT is associated with thrombosis. Early symptoms of drug-induced thrombocytopenia include increased bruising, petechiae, ecchymoses, and epistaxis. Bleeding from mucous membranes and severe purpura can appear later in the disorder. A list of medications (excluding cancer chemotherapeutic agents) associated with drug-induced thrombocytopenia can be found in Table 112–6.

Most of the drugs that induce thrombocytopenia by their toxic effects are cancer chemotherapy agents, but organic solvents, pesticides, drugs that influence folic acid metabolism, and inamrinone (formally named amrinone) have also been implicated. Although orally administered inamrinone has been reported to cause thrombocytopenia in up to 18.6% of patients,[92] only the intravenous formulation is currently commercially available in the United States. Some studies suggest that this toxic effect might be caused by the metabolite of inamrinone, instead of the parent drug.[93] Regardless of the cause, inamrinone use has been largely replaced by other phosphodiesterase-3 inhibitors that are not associated with the same high risk of side effects.

The agents most commonly implicated in immune-mediated thrombocytopenia are quinine, quinidine, gold salts, sulfonamide antibiotics, rifampin, glycoprotein IIb/IIIa (GPIIb/IIIa) receptor antagonists, and heparin.[91] Studies of these agents have helped to elucidate the mechanisms of drug-induced immune thrombocytopenia. In hapten-type reactions, the offending drug binds covalently to certain platelet glycoproteins. Antibodies are generated that bind to these drug-bound glycoprotein epitopes. After the binding of antibodies to the platelet surface, lysis occurs through complement activation or through clearance from the circulation by macrophages.[94] Hapten-mediated immune thrombocytopenia usually occurs at least 7 days after the initiation of the drug, although it can occur much sooner if the exposure is actually a reexposure to a previously administered drug. The recovery period, once the suspected drug is discontinued, is often short in duration with a median recovery time within 1 week.[95] Although relatively rare, penicillins and cephalosporins can cause thrombocytopenia through this mechanism.[90]

Quinine, anticonvulsants, and nonsteroidal anti-inflammatory medications are thought to induce thrombocytopenia through the drug-dependent antibody mechanism.[91] This mechanism is slightly different from the hapten-type mechanism. In this type of reaction it is thought that antibodies exist within the patient's circulation that recognize an epitope on the platelet glycoprotein, but this recognition is too weak to result in antibody binding to the platelet surface. However, the drug contains structural elements that are noncovalently complementary to regions of the antibody and the glycoproteins on the platelet surface. This causes an improved fit or increased K_A between the antibody and the platelet surface, with the drug "trapped" in between, resulting in antibody binding of platelet.[91] A recently published study suggests that vancomycin-induced thrombocytopenia is related to drug-dependent antibodies.[96,97]

Eptifibatide and tirofiban are platelet glycoprotein IIb/IIIa receptor antagonists that prevent platelet activation and binding of fibrinogen, thereby inhibiting platelet thrombus formation. In clinical trials and postmarketing studies it was found that approximately 0.1% to 2% of patients treated with these medications experienced acute profound thrombocytopenia within several hours of their first exposure to the drug.[91,97] This acute drop in platelets without prior drug exposure

suggested initially that this reaction was mediated by a nonimmune mechanism. However, a plausible immune-mediated mechanism has since been proposed. After binding to the GPIIb/IIIa receptor, these medications cause a conformational change in the receptor that allows it to be recognized by naturally occurring antibodies already in the patient's blood (i.e., a ligand-induced binding site). In contrast to the two previously discussed immune-mediated mechanisms (hapten-type and drug dependent), the drug is not present within the binding between the antibody and the platelet surface. The drug has been removed from the platelet surface before the antibody binds, but the conformational change in the GPIIb/IIIa receptor remains.[91]

Abciximab, a GPIIb/IIIa receptor antagonist like tirofiban and eptifibatide is also associated with thrombocytopenia. Abciximab-induced thrombocytopenia appears to occur through a different drug-specific antibody mechanism as opposed to a ligand-induced binding site mechanism with eptifibatide and tirofiban. Unlike tirofiban and eptifibatide, abciximab is a chimeric (human–mouse) monoclonal antibody. As such, it is not surprising that this molecule may exhibit some immunogenic properties. It has been demonstrated that patients who experience thrombocytopenia after the administration of abciximab have circulating antibodies that directly recognize the drug. Because the drug is bound to platelets, thrombocytopenia results. Approximately 2% of patients experience thrombocytopenia with the first administration, and 10% to 12% with subsequent administrations.[98,99] Further, in those patients who experience the reaction with the first administration, some experience immediate thrombocytopenia, while in a small subset of patients, this does not occur until approximately a week after drug administration. In patients who experience immediate thrombocytopenia, drug-specific antibodies are naturally occurring and present at the time of drug administration. For those with a delayed response (6 to 8 days later), drug-specific antibodies are produced during this time, and because abciximab remains bound to platelets for up to 2 weeks, the reaction can still occur.[100] Because all three GPIIb/IIIa receptor antagonists are coadministered with heparin, it is important to distinguish between GPIIb/IIIa receptor antagonist-induced and heparin-induced thrombocytopenia. A heparin-induced platelet aggregation study can help to determine the offending agent. Pseudothrombocytopenia, defined as in vitro platelet aggregation in blood anticoagulated with ethylenediamine tetraacetic acid (EDTA), is clinically insignificant, but it must also be differentiated from thrombocytopenia induced by GPIIb/IIIa receptor antagonists. In this case, microscopic examination of a peripheral blood smear, along with repeated platelet counts in citrate-anticoagulated blood samples, makes the distinction possible.[101]

CLINICAL CONTROVERSY

Profound thrombocytopenia (i.e., platelet count less than 20,000 cells/mm^3 [20 × 10^9/L]) has been reported with the GPIIb/IIIa receptor antagonists. Before this effect was fully appreciated, many clinicians attributed this event to heparin. The current challenge for clinicians is to distinguish between GPIIb/IIIa receptor antagonist-induced and heparin-induced thrombocytopenia, so that the patient's adverse event is documented properly. Thrombocytopenia associated with GPIIb/IIIa receptor antagonists can present with a nadir of platelet counts of 1,000 to 4,000 cells/mm^3 (1 to 4 × 10^9/L) occurring from 2 to 31 hours following bolus infusion, which is much sooner than the 5 to 10 days observed with initial heparin exposure. However, reexposure to heparin can produce profound thrombocytopenia within hours. The ubiquity of heparin use for flushing catheters makes it difficult to determine previous exposure in many cases. Clinicians can choose from several types of assays to aid in the diagnosis of heparin-induced thrombocytopenia, including platelet activation assays, platelet aggregation studies, and enzyme-linked immunosorbent assay methods, each with varying sensitivity, specificity, and availability.

Gold compounds and procainamide appear to induce thrombocytopenia through the platelet-specific autoantibody-type reaction.[90] In this type of reaction, a drug induces the production of autoantibodies that bind to platelet membranes and cause destruction, but the causative drug does not have to be present for the reaction to occur. In contrast, the drug-dependent antibody reaction requires the presence of the drug to allow antibody binding. Although several mechanisms of drug-induced thrombocytopenia have been proposed, it is often not possible to determine the mechanism for an individual drug or patient, and more than one mechanism can be responsible for the condition.

The final type of immune-mediated thrombocytopenia has been categorized as immune complex–induced thrombocytopenia.[91] This describes the mechanism of the most serious type of heparin-induced thrombocytopenia, HIT type II.

At least two types of heparin-induced thrombocytopenia (HIT) have been identified. The most common, type I, occurs in approximately 10% to 20% of patients treated with heparin.[102] It is a mild, reversible, nonimmune-mediated reaction that usually occurs within the first 2 days of therapy.[6] The platelet count slowly returns to baseline following an initial decline, despite continued heparin therapy. HIT type I is usually an asymptomatic condition and is thought to be related to platelet aggregation.[6]

HIT type II is less common but more severe and can be associated with more complications. Approximately 1% to 5% of patients receiving unfractionated heparin and up to 0.8% of patients receiving low-molecular-weight heparin (LMWH) can develop HIT.[6,102] Patients typically present with a low platelet count (e.g., below 150,000 cells/ mm^3 [150×10^9/L]) or a 50% or more decrease in platelet count from baseline, and thrombosis can occur.[103] The platelet count generally begins to decline 5 to 10 days after the start of heparin therapy. However, this decline can occur within hours of receiving heparin if the patient has recently received heparin (i.e., within 100 days).[103] Thrombocytopenia and thrombosis can develop with low-dose heparin,[104] heparin-coated catheters,[105] or even heparin flushes. Certain patient populations have a higher risk for developing HIT than others; patients who have had recent, major surgery are one of the highest-risk groups.[102] The next highest risk groups include patients receiving heparin for thrombosis prophylaxis following peripheral vascular surgery, cardiac surgery, and orthopedic surgery.[106] A lower incidence is seen in medical, obstetric, and pediatric patients, especially those receiving LMWH instead of unfractionated heparin.[102] The most recent practice guidelines by the American College of Chest Physicians recommend varying degrees of platelet monitoring based on the relative risk of developing HIT.[107]

HIT is caused by the development of antibodies against platelet factor-4 (PF-4) and heparin complexes[103] (Fig. 112–5). Low-molecular-weight heparins bind less well to PF-4 than unfractionated heparin, and therefore antibody formation is less common. However, there is cross-reactivity between antibodies developed by patients receiving unfractionated heparin and LMWH; thus LMWH should not be used in patients with HIT.[102] Once the antibodies bind to the complexes, platelet activation and aggregation occur, with subsequent release of more circulating PF-4 to interact with heparin. In addition, procoagulant microparticles are also released that increase the risk of thrombosis.[102] Thrombosis is one of the major complications of HIT and can occur in up to 20% to 50% of patients with HIT.[103] In fact, thrombosis is the precipitating factor that leads the clinician to diagnose HIT in many patients. This high risk of thrombosis continues for days to weeks after heparin discontinuation and platelet recovery, and continued anticoagulation with an alternative agent is essential during this time period.[103] Other less frequent manifestations of HIT include heparin-induced skin necrosis and venous gangrene of the limbs.[102,103] The diagnosis of HIT is frequently a clinical one, supported by laboratory testing. Several types of assays are available to aid in the diagnosis of HIT,

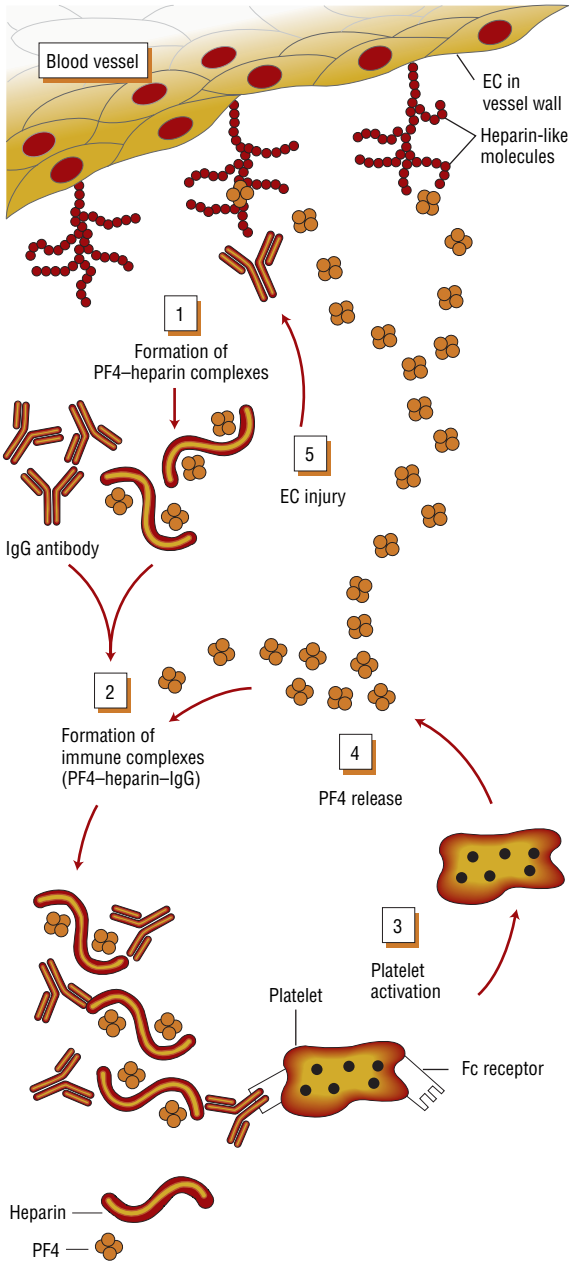

FIGURE 112-5. Proposed explanation for the presence of both thrombocytopenia and thrombosis in heparin-sensitive patients who are treated with heparin. Injected heparin reacts with platelet factor-4 (PF-4), which is normally present on the surface of endothelial cells (ECs) or released in small quantities from circulating platelets, to form PF-4–heparin complexes *(1)*. Specific immunoglobulin G (IgG) antibodies react with these conjugates to form immune complexes *(2)* that bind to crystallizable fragment (Fc) receptors on circulating platelets. Fc-mediated platelet activation *(3)* releases PF-4 from α-granules in platelets *(4)*. Newly released PF-4 binds to additional heparin, and the antibody forms more immune complexes, establishing a cycle of platelet activation. PF-4 released in excess of the amount that can be neutralized by available heparin binds to heparin-like molecules (glycosaminoglycans) on the surface of ECs to provide targets for antibody binding. This process leads to immune-mediated EC injury *(5)* and heightens the risk of thrombosis and disseminated intravascular coagulation. *(Aster RH. Heparin-induced thrombocytopenia and thrombosis. N Engl J Med 1995;332:1374–1376. Copyright © 1995 Massachusetts Medical Society. All rights reserved.)*

including platelet activation assays, platelet aggregation studies, and enzyme-linked immunosorbent assay methods, each with varying sensitivities and specificities.[6]

TREATMENT

Drug-Induced Thrombocytopenia

The primary treatment of drug-induced thrombocytopenia is removal of the offending drug and symptomatic treatment of the patient. The use of corticosteroid therapy in the treatment of drug-induced thrombocytopenia is controversial, although some authors recommend it in severe symptomatic cases.[108]

In the case of HIT, the main goal of management is to reduce the risk of thrombosis or reduce thrombosis-associated complications in patients who have already developed a clot. All forms of heparin must be discontinued, including heparin flushes, and alternative anticoagulation must begin immediately.[109] The direct thrombin inhibitors are the alternative anticoagulants most commonly used in current practice. Three direct thrombin inhibitors are currently available: lepirudin, argatroban, and bivalirudin. Lepirudin, the first drug that was approved for the treatment of HIT, is a recombinant analogue of hirudin, a natural anticoagulant found in leeches. Lepirudin is renally eliminated and requires dosage adjustment in those patients with kidney dysfunction. It is also important to note that antibodies to lepirudin develop in approximately 30% of patients who receive this agent for the first time, and it is therefore recommended that patients receive only one treatment course of lepirudin.[103] Argatroban is another intravenous thrombin inhibitor indicated for the management of HIT. But unlike lepirudin, argatroban is metabolized in the liver and can be used in patients with end-stage renal disease. However, dosage adjustment is needed for patients with significant hepatic impairment. The most recently approved direct thrombin inhibitor is bivalirudin. It is similar to lepirudin in that is a parenteral bivalent analogue of hirudin. It requires dosage adjustment only in severe renal failure. Fondaparinux, an anticoagulant pentasaccharide that inhibits factor Xa, has been proposed by some as a potential treatment for HIT because it does not appear to cause in vitro cross-reactivity with HIT antibodies.[110,111] Clinical data, however, to support the use of fondaparinux in the treatment of HIT-induced thrombosis are lacking. The most recent guidelines by the American College of Chest Physicians suggest that fondaparinux is most appropriately used in patients at relatively low risk of having HIT but for whom the use of either UFH or LMWH is not desired.[107] These agents should also be considered for the treatment of patients who have acute HIT without thrombosis because of the increased risk of thrombosis occurring in these patients. Because of the increased risk of venous limb gangrene, warfarin should not be used alone to treat acute HIT complicated by deep vein thrombosis.[107]

SUMMARY

7 Drug-induced hematologic disorders are rare but potentially life-threatening conditions. Clinicians should be cognizant of medications with the potential of causing hematologic disorders and educate patients to recognize the symptoms associated with such events. Frequent laboratory monitoring of patients taking medications associated with severe hematologic events can facilitate diagnosis and treatment. Identifying the etiology of the event and documenting the causative agents can serve to prevent a recurrence secondary to the use of a related medication. Reporting these events to national adverse event reporting services and in the peer-reviewed medical literature can serve to improve the understanding of the prevalence and risk factors for this disorder.

ABBREVIATIONS

ADR: adverse drug reaction
ATG: antithymocyte globulin
DAT: direct antiglobulin test
EDTA: ethylenediamine tetraacetic acid
Fc: crystallizable fragment (of immunoglobulin)
G6PD: glucose-6-phosphate dehydrogenase
G-CSF: granulocyte colony-stimulating factor
GM-CSF: granulocyte-macrophage colony-stimulating factor
GPIIb/IIIa: glycoprotein IIb/IIIa
GVHD: graft-versus-host disease
HIT: heparin-induced thrombocytopenia
HLA: human leukocyte antigen
HSCT: hematopoietic stem cell transplantation
IgG: immunoglobulin G
IgM: immunoglobulin M
LMWH: low-molecular-weight heparin
NADPH: reduced nicotinamide adenine dinucleotide phosphate
PF-4: platelet factor-4
RBC: red blood cell
WBC: white blood cell

INFECTIOUS DISEASES

CHAPTER 113

Laboratory Tests to Direct Antimicrobial Pharmacotherapy

MICHAEL J. RYBAK, JEFFREY R. AESCHLIMANN, AND KERRY L. LAPLANTE

KEY CONCEPTS

1. Familiarity with normal host flora and typical pathogens will help to determine whether a patient is truly infected or merely colonized.
2. Direct examination of tissue and body fluids by Gram stain provides simple and rapid information about the causative pathogen.
3. Isolation of the offending organism by culture assists in the diagnosis of infection and allows for more definitive directed treatment.
4. The development of molecular testing systems has improved our ability to diagnose infection and determine the antimicrobial susceptibilities for numerous fastidious or slow growing pathogens, such as mycobacteria and viruses.
5. Although highly standardized, in vitro antimicrobial susceptibility testing has limitations and often cannot truly mimic the conditions found at the site of an infection. This can cause discordance between in vitro susceptibility results and in vivo response to therapy.
6. The laboratory evaluation of antimicrobial activity is an important component of the pharmacotherapeutic management of infectious diseases.
7. Antimicrobial pharmacodynamics have become a crucial consideration the selection of both empirical and pathogen-directed therapy in the current era of antimicrobial resistance.
8. When used appropriately, rapid automated susceptibility test systems appear to improve therapeutic outcomes of patients with infection, especially when they are linked with other clinical information systems.
9. Laboratory tests such as minimal bactericidal concentration tests, time-kill tests, post-antibiotic effect tests, and antimicrobial combination testing are important for the clinician to understand because they help to determine antimicrobial pharmacodynamic properties.
10. Routine monitoring of serum concentrations is currently used for a select few antimicrobials (e.g., aminoglycosides, chloramphenicol, and vancomycin) in an attempt to minimize toxicity and maximize efficacy.
11. Appropriate timing for the collection of serum samples when measuring antimicrobial serum concentrations is crucial to ensure that proper data are generated on the pharmacokinetics of antimicrobials.
12. The monitoring of aminoglycoside serum concentrations and the use of extended-interval doses can help to maximize the probability of therapeutic success and minimize the probability of aminoglycoside-related toxicity.
13. Vancomycin and aminoglycoside serum concentration monitoring should be routinely done to ensure adequate serum concentrations, minimize toxicity, and avoid the potential for resistance.
14. Optimization of antimicrobial pharmacodynamic parameters such as the ratio of the peak serum concentration to minimum inhibitory concentration or the time that the serum concentration remains above the minimum inhibitory concentration and area above the curve over minimum inhibitory concentration can improve infection treatment outcomes.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Selection of an appropriate antimicrobial therapeutic regimen for a given infectious disease requires knowledge of the infecting pathogen, host characteristics, and the drug's expected activity against the pathogen. The most fundamental aspect of therapy starts with an appropriate diagnosis. A vast array of laboratory tests is available to assist in verifying the presence of infection and for monitoring the response to therapy. Although useful, these tests are subject to interpretation and cannot be substituted for sound clinical judgment. Organism susceptibility to the administered antimicrobials is key to determining the outcome from therapy. Host characteristics, however, such as immune status, infection site location, and body organ function, play

a significant role in selecting the most appropriate antimicrobial for a given individual.[1] This chapter reviews the routine laboratory tests that are used to assist in the diagnosis and treatment of infection.

LABORATORY TESTS CONFIRMING THE PRESENCE OF INFECTION

NONSPECIFIC TESTS

Many tests are used to determine whether a patient has an infection. Although no single test can prove that a patient is infected, when used in combination with clinical findings, tests are helpful to establish the diagnosis of infection. Because many tests are nonspecific, there are factors other than infection that can cause a test to be reported as positive when no infection exists. Therefore, the importance of careful interpretation and sound clinical judgment cannot be overemphasized.

White Blood Cell Count and Differential

Understanding the role of the white blood cell (WBC) in fighting infection is important in the diagnosis of infection, the selection of drug therapy, and the monitoring of patient progress. The major role of the WBC is to defend the body against invading organisms such as bacteria, viruses, and fungi. The typical normal range of the WBC is 4,500 to 11,000 cells/mm^3 and depends on many factors such as patient age, gender, sample population and test method. White blood cells usually are elevated in response to infection. The WBC count can also become elevated in response to noninfectious causes, including stress, inflammatory conditions such as rheumatoid arthritis, and leukemia or in response to certain drugs (e.g., corticosteroids).

White blood cells are divided into two groups: the granulocytes, which have prominent cytoplasmic granules, and the agranulocytes, which lack granules. Polymorphonuclear (PMN) granulocytes are made up of neutrophils, basophils, and eosinophils. The two other classes of WBCs are the monocytes and lymphocytes. Neutrophils are the most common type of WBCs in the blood, comprising approximately 70% of the total WBC count. In response to infection, they leave the bloodstream and enter the tissue to interact with and phagocytize offending pathogens. Mature neutrophils sometimes are referred to as *segs* because of their segmented nucleus, which usually consists of two to five lobes. Immature neutrophils lack this segmented feature and are referred to as *bands*. During an acute infection, immature neutrophils, such as bands (single-lobed nucleus), are released from the bone marrow into the bloodstream at an increased rate, and the percentage of bands (usually 5%) can increase in relationship to mature cells. The change in the ratio of mature to immature cells is often referred to as a "shift to the left"because of the way the cells were counted by hand with a microscope and charted from immature to mature cells.

Leukocytosis, an increase in WBCs, is a normal host defense to infection. Unfortunately, bacterial infection is a common complication of neutropenia from cancer chemotherapy. Neutropenia occurs when the bone marrow does not produce enough WBCs to fight infection. Patients who are neutropenic are incapable of increasing their WBCs in response to infection. In fact, susceptibility to infection in these patients is highly dependent on their WBC status. Patients with neutrophil counts of less than 500 cells/mm^3 are at high risk for the development of bacterial or fungal infections. The absence of leukocytosis also occurs in the elderly and in severe cases of sepsis.[2,3]

Lymphocytes comprise 15% to 40% of all WBCs and are of central importance to the immune system. Two functional types of lymphocytes are the T cell, which is involved in cell-mediated immunity, and the B cell, which produces antibodies involved in humoral immunity. Lymphocytosis is frequently associated with acute viral infections such as Epstein-Barr virus infection (mononucleosis) and Cytomegalovirus (CMV) infection and rarely with unusual bacterial infections (i.e., *Brucella* species infections).

T lymphocytes are characterized on the basis of function (i.e. T-helper cells, Th_1 and Th_2) and on the basis of surface protein. Most type 1 and type 2 T cells carry a T4 (CD4) marker that recognizes class II major histocompatibility complex (MHC) antigens, and most cytoxic T cells carry a T8 (CD8) marker that recognizes class I MHC antigens. A severe deficiency of CD4 cells is associated with human immunodeficiency virus (HIV) infection and opportunistic infections.[4] Malignancies also can adversely affect cellular immunity. Patients with Hodgkin's disease and other types of lymphoma exhibit defective cell-mediated immunity that predisposes them to a variety of infections, notably fungal diseases and infections by the *Listeria* species. Drug treatment with cytotoxic chemotherapy and corticosteroids also can have profound deleterious effects on cell-mediated immunity.[5] Defects in cell-mediated immune function can be demonstrated by a variety of simple laboratory tests, including quantification of lymphocytes on a routine complete blood cell count and skin testing for anergy. A more detailed investigation includes quantitative measurements of $CD4^+$ and $CD8^+$ cells. Monocytosis is correlated less frequently with acute bacterial infection, although its presence has been associated with the response of certain infections (e.g., tuberculosis) to chemotherapy. Eosinophilia can result from parasitic infection.[6] Figure 113–1 describes a number of cell types and their biologic function.

Cell type	Cellular function	
Macrophage/monocyte	Antigen presenting cell Surveillance of foreign antigens	
Neurophils	Defense against bacteria and fungus	
Eosinophils	Defense against parasites Response against allergic reactions	
Basophil	Allergic response	
B lymphocyte	Antibody production Antigen presenting cell	
T lymphocytes	Cellular immunity against virus and tumors Regulation of the immune system

TABLE 113-1 Examples of Normal Bacterial Flora

	Gram-Positive		Gram-Negative		
	Cocci	***Rods***	***Cocci***	***Rods***	***Other***
Skin	*Staphylococcus* spp (e.g., S. epidermidis), *Streptococcus* spp	*Corynebacterium* spp, *Propionibacterium* spp		Enteric bacilli (some sites), *Acinetobacter* spp (Coccobacilli)	
Oropharynx	Streptococci–viridans group Micrococcus	*Corynebacterium* spp	Neisseria	*Haemophilus* spp	Spirochetes
Gastrointenstinal tract	*Enterococcus* spp, *Peptostreptococcus* spp	*Lactobacillus, Clostridium*		*Bacteroides* spp, Enteric bacilli (*E coli, Klebsiella* spp)	
Genital tract	*Streptococcus* spp, *Staphylococcus* spp	*Lactobacillus, Corynebacterium* spp		Enterobacteriacea, *Prevotella* spp	*Mycoplasma*

Other Tests

Some nonspecific laboratory tests are useful to support the diagnosis of infection. The inflammatory process initiated by an infection sets up a complex host response. Activation of the nuclear factor-κ_B (NF-κ_B) transcription factors plays an important role in the regulation of the immune system. NF-κ_B is activated by bacterial and viral antigens, which lead to the production of proinflammatory cytokines and chemokines. The rapid detection of activated NF-κ_B can be measured by transcription factor enzyme-linked immunoassay (TF-ELISA) during a systemic inflammatory response syndrome (SIRS) and is considered to be crucial for the treatment of patients with septicemia. Acute-phase reactants, such as the erythrocyte sedimentation rate (ESR) and the C-reactive protein concentration, are elevated in the presence of an inflammatory process but do not confirm the presence of infection because they are often elevated in noninfectious conditions, such as collagen-vascular diseases and arthritis. Large elevations in ESR are associated with infections such as endocarditis, osteomyelitis, and intraabdominal infections.[8,9]

Changes in endothelial membranes and the presence of a foreign pathogen and its endotoxins cause inflammatory cytokines, such as interleukin 1 (IL-1), IL-6, and IL-8 and tumor necrosis factor-α (TNF-α), to be produced by macrophages or lymphocytes. Fluctuations in cytokine levels occur during the course of an infection, which can be useful in staging and monitoring the response to therapy. Although abnormally high levels of TNF have been associated with a variety of noninfectious causes, spiked elevations in TNF are found in patients with serious infections, such as sepsis. Studies of the relationship of circulating mediators to patient outcome have determined the value of endotoxin and cytokine measurements in patients with sepsis. Although the combination of elevations in endotoxin and individual cytokines has correlated well with the mortality rate, measurement of IL-6 was by far the best individual cytokine that predicted patient outcome.[9] Understanding the balance between these proinflammatory and antiinflammatory processes likely will lead to interventions that can have a direct impact on the outcome of patients with sepsis.[11]

LABORATORY IDENTIFICATION OF PATHOGENS

COLONIZATION VERSUS INFECTION

1 Pathogens are organisms that are capable of damaging host tissues and that elicit specific host responses and symptoms that are consistent with an infectious process. These organisms are transferred from patient to patient, vector to patient (animals, insects, and so on), environment to patient (e.g., hospital settings) or are derived from the patient's own flora. Conversely, the human body contains a vast variety of microorganisms that colonize body systems and make up the so-called normal flora. These organisms occur naturally in the tissues of the host and provide some benefits, including defense by occupying space, competing for essential nutrients, stimulating cross-protective antibodies, and suppressing the growth of potentially pathogenic bacteria and fungi (Table 113–1).

Organisms that comprise the normal flora can become pathogenic when host defenses become impaired or if they are translocated to other body sites during trauma. The identification of an organism that is considered to be normal flora in a wound or otherwise sterile body cavity or fluid often becomes a dilemma for the clinician in deciding whether or not a patient is infected and whether or not the patient requires treatment. Such is the case with *Staphylococcus epidermidis* when it is identified in the blood of a hospitalized patient. *S epidermidis* is considered normal skin flora and commonly colonizes intravenous catheters. In these conditions, identification of the organism must be taken in light of the patient circumstances (signs and symptoms, laboratory indices supporting infection) and the probability of the organism being responsible for the infection. Often the simple removal of the catheter can eliminate the organism from the bloodstream, thereby preventing misdiagnosis and unnecessary application of antimicrobials.[12]

DIRECT EXAMINATION

2 Direct examination of tissue or body fluids believed to be infected can provide simple, rapid information to the clinician. Microscopic examination of wet-mount specimen preparations can provide valuable information regarding potential pathogens. Applications of this procedure with or without staining preparations include direct examination of sputum, bronchial aspirates, scrapings of mucosal lesions, and urinary sediment. The Gram stain is one of the first identification tests run on a specimen brought to the laboratory. For this procedure, crystal violet is applied as the primary stain, with iodine added to enhance the staining process and to form a crystal violet–iodine complex. Alcohol decolorization is the next step in the procedure. Gram-negative cells are decolorized by the addition of alcohol, and they take in a red color when counterstained by safranin. Gram-positive cells are not decolorized by alcohol and retain the crystal violet color and appear purple. Gram staining in conjunction with microscopic examination can provide a presumptive diagnosis and some indication of the organism's morphologic characteristics (gram-positive, gram-negative, gram-variable, bacillus, or cocci). This is extremely useful information for the selection of empirical antibiotic therapy.

Gram stains are performed routinely on cerebrospinal fluid (CSF) in cases of suspected meningitis, on urethral smears for venereal diseases, and on abscess or effusion specimens. They are helpful in identifying organisms that may not grow on culture and which otherwise would be missed. Although Gram stains of sputum are performed routinely when respiratory tract infections are suspected, there is controversy regarding the usefulness of this test because the sputum is often contaminated with mixed or normal flora. The predominance of one particular organism, the overall

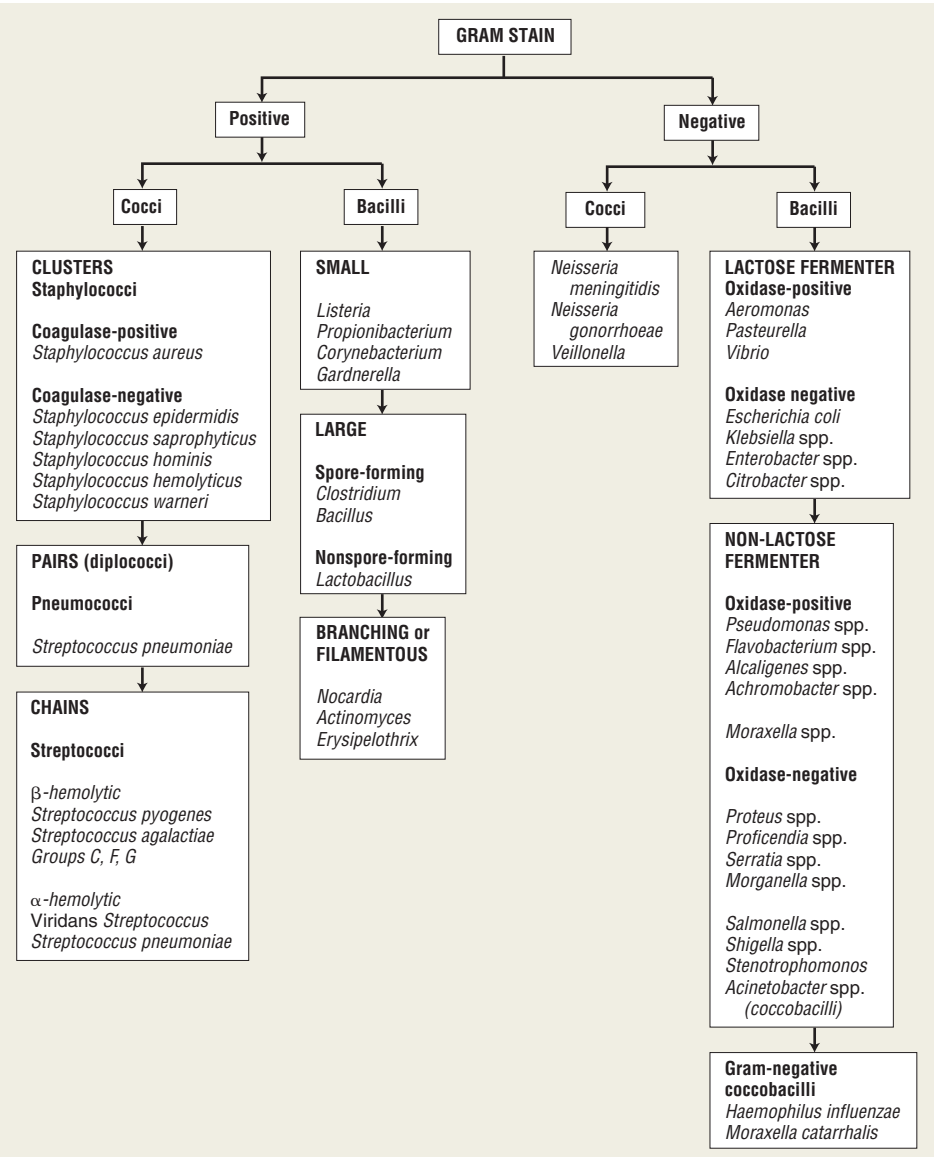

FIGURE 113-2. Important bacterial pathogens classified according to Gram stain and morphologic characteristic.

number of organisms present, the amount of PMN granulocyte present, and the presence or absence of a significant amount of squamous epithelial cells (<10 per low-power field) can improve the significance of the sputum Gram stain specimen. Figure 113–2 lists some common infecting pathogens grouped according to Gram stain and other characteristics.

Other staining techniques are used to identify pathogens such as those that are best identified microscopically because of their poor growth characteristics in the laboratory setting. The best examples of these are the Ziehl-Neelsen stain for acid-fast bacilli, which is used for the identification of mycobacteria species, and the India ink, potassium hydroxide (KOH), and Giemsa stains, which are useful for detecting certain fungi.[13]

CULTURES

3 Isolation of the etiologic agent by culture is the most definitive method available for the diagnosis and eventual treatment of infection. Although suspicion of a specific pathogen or group of pathogens is helpful to the laboratory for the selection of a specific cultivating medium, the more common procedure for the laboratory is to screen for the presence of any potential pathogen. After receipt of a clinical specimen, the laboratory will inoculate the specimen in a variety of artificial media. Some culture media are designed to differentiate various organisms on the basis of biochemical characteristics or to select specific organisms on the basis of resistance to certain antimicrobials. Other media are employed commonly for the isolation of more fastidious organisms, such as *Listeria, Legionella*, *Mycobacterium*, or *Chlamydia*. Cultures for viruses are more difficult to perform and are undertaken primarily by larger institutions or outside laboratories because of the technical expense and time involved in processing samples.

When a culture is obtained, careful attention must be paid to ensuring that specimens are collected and transported appropriately to the laboratory. Every effort should be made to avoid contamination with normal flora and to ensure that the specimen is placed in the appropriate transport medium. Culture specimens should be transported to the laboratory as soon as possible because organisms can perish from prolonged exposure to air or drying. This is especially important for swab specimen preparations. Transport media may not be ideal for all organisms. Specimens that contain fastidious organisms or anaerobes require special transport media and should be forwarded immediately to the laboratory for processing. Finally, the source of the specimen should be clearly recorded and forwarded along with the culture to the laboratory. This process will aid the laboratory in differentiating true pathogens

from the expected normal flora, and it will help in the selection of the appropriate culture media. Detection of microorganisms in the bloodstream by standard culturing techniques is difficult because of the inherently low yield of organisms diluted by blood, humoral factors with bactericidal activity, and the potential of antimicrobial pretreatment affecting organism growth. Most blood collection bottles dilute the blood specimen 1:10 with growth medium to neutralize the bactericidal properties of blood and antimicrobials. The addition of a polyanionic anticoagulant abolishes the effect of complement and antiphagocytic activity in the specimen. Some laboratories also add β-lactamase to their blood collection bottles.

Rapid detection of bacteria or fungi within a few hours of specimen collection is now possible by the use of automated culturing systems, such as BACTEC (Becton Dickinson Diagnostic Instruments, Sparks, MD), that use bottles of growth medium containing a fluorescent sensor to monitor culture bottles every 10 minutes for the presence of carbon dioxide (CO_2) as a by-product of microorganism growth. Computers monitoring the system alert laboratory personnel of positive culture results by both audible and visual alarms. Once detected, a battery of testing can be performed rapidly that shortens the reporting time and that enables clinicians to obtain preliminary information about the organism.[13,14] The initial identity of the organism can be determined by a variety of testing procedures. General schemes differentiate organisms into primary groups, such as Gram-positive and Gram-negative bacteria. This can be accomplished by simple Gram staining, as described previously, by evaluating organism growth patterns on selective media, and by testing for the presence or absence of specific enzymes and chemical characteristics, such as hemolytic and fermentation properties. For example, non–lactose-fermenting gram-negative bacilli that are oxidase-positive can suggest *Pseudomonas aeruginosa* as opposed to a variety of other potential gram-negative organisms. This preliminary information, which is readily obtainable from the laboratory, can greatly assist the clinician in choosing the appropriate empirical therapy. Definitive identification of organisms requires more complex testing procedures and devices that can further differentiate the organism on the basis of specific fermentation and biochemical reactive properties. Commercially available automated systems can inoculate the test organism into a series of panels containing a variety of test media, sugars, and other reagents. The system can then photo-metrically determine the results and compare the findings to a library of organism characteristics to produce a definitive identification.[14]

Viral agents can be detected by direct observation of inoculated culture cells for cytopathic effects or by detection of antigens after incubation by immunofluorescent methods. The culture method is most useful for organisms such as CMV or herpes simplex virus because these viral agents are rapidly propagated in culture cells, making them easily detected.[15]

DIAGNOSIS OF INFECTION USING IMMUNOLOGIC AND MOLECULAR METHODS

ANTIBODY AND ANTIGEN DETECTION

4 The use of immunologic methods for the diagnosis and monitoring of human host immune response to infection has become an indispensable laboratory tool. This is especially important in the detection of microorganisms, such as bacteria, fungi, and viruses, that otherwise would elude detection or severely delay results from conventional culturing techniques. The primary immunologic methods involve the detection and quantification of antibodies directed against a specific pathogen or its components. These methods have the advantage of a rapid turnaround time and an acceptable level of sensitivity and specificity. Some tests (e.g., identification of group A streptococci and the Rapid Influenza diagnostic test) are simple to use, can be performed conveniently in the physician's office, and often can be used to decide whether antimicrobials should be administered for a suspected infection. Limitations with these tests exist as antigens will still exist even if the pathogen is not longer alive, hence allowing for a false positive test. In addition, the positive test result indicating the presence of the pathogen does not assist in determining if the patient was infected or simply colonized with the pathogen.

Antibody or antigen detection can be accomplished by a variety of techniques, including immunofluorescence, which has been used routinely for the detection of CMV, respiratory syncytial virus, varicella-zoster virus, *Treponema pallidum* (syphilis), *Borrelia burgdorferi* (Lyme disease), and *Chlamydia trachomatis*. Latex agglutination is useful for detecting meningococcal capsular antigens in CSF of patients suspected of having bacterial meningitis and as an aid in the diagnosis of *Legionella pneumophila*. Enzyme-linked immunosorbent assay (ELISA) is a commonly employed method for detecting HIV, herpes simplex virus, respiratory syncytial virus, pneumococcal serum antibody, *Neisseria gonorrhoeae*, and *Haemophilus pylori*.[15]

MOLECULAR TECHNIQUES FOR THE DETECTION OF MICROORGANISMS

Hybridization DNA Probes

4 Highly sensitive and specific molecular methods are now available for the rapid detection and identification of a variety of pathogens. The two primary molecular techniques used commonly are nucleic acid hybridization, which involves the binding of a specific DNA or RNA probe to its target, and DNA amplification schemes. Probe-based methods require the extraction of DNA or RNA from a clinical specimen (i.e., body fluid, tissue, or WBC) or directly from a microorganism culture. The extract is then tested for the presence of pathogen DNA or RNA using a probe that contains a specific oligonucleic acid–based sequence for the organism. For example, a probe with a sequence of ACTGTT would bind to the complementary organism nucleic acid sequence of TGACAA. Because the probe is labeled with a signal-emitting molecule (i.e., radiolabeled, colorimetric, or chemoluminescent), a match would be detected.

The primary means for detection involves the use of separation of the organism DNA into specific fragments (gel electrophoresis), transfer and fixation of the mixture to specialized paper or nylon membranes (Southern or Northern blotting), the mixing of the DNA fragments with the labeled probe (hybridization), and transfer to radiographic or photographic film for processing. These techniques have been used for many years and are fairly standardized methods for the detection of a variety of organisms. Hybridization probes are useful for a variety of diagnostic and clinical applications, including the direct examination of organisms in tissue, which enables the evaluation and documentation of organism infestation, location, distribution, and host response. The use of hybridization probes is particularly helpful for the detection of slow-growing organisms such as *Mycobacterium tuberculosis*, *N gonorrhoeae*, and certain species of fungi. This technique is also used to document the presence or absence of antimicrobial-resistant genes in a cell culture and to track the spread of resistant microorganisms in hospital and outpatient settings. Although employed widely, the use of hybridization probes is often limited by their lack of sensitivity. Probe amplification methods are available that improve the sensitivity of these assays. The principle

of these probe-amplification schemes is to boost the probe's signal-emitting molecule to make it more easily detected. A more advanced signal-amplification system available is the branched DNA (bDNA) probe system (Chiron Corp., Emeryville, CA) which is often used to identify retroviruses such as HIV. This system uses multiple probes and multiple signal-emitting molecules (reporters). The target-binding probe contains two hybridization regions. One region is complementary to the target, and the other region is capable of binding with the bDNA amplification multimer. The amplification multimer binds multiple reporter molecules (as many as 3,000), which provides a significant boost in the probe's signal. Branched DNA probe systems are being developed for rapid detection of hepatitis B and C, HIV-1, and CMV. Because of the system's high specificity and quantitative ability, bDNA probe assays can be useful for therapeutic monitoring, such as in the case of monitoring the response to antiretroviral therapy in acquired immunodeficiency syndrome (AIDS).[16,17]

Nucleic Acid Amplification Methods

Nucleic acid amplification methods are now considered a standard laboratory tool. They have had a tremendous impact on the diagnosis and treatment of infectious diseases. These highly sensitive methods have the capability to detect and quantitate minute amounts of target nucleic acid in a rapid manner. The polymerase chain reaction (PCR) is based on the capability of a DNA polymerase to copy and elongate a targeted strand of DNA. This is accomplished by the use of short oligonucleotide primers (20 to 25 nucleotides long) that correspond to the DNA targeted to be expanded. After an excess of primers and heat-stable DNA polymerases are added to the targeted DNA mixture, the targeted DNA is denatured and separated by a process of cycling hot and cool temperatures. Each cycle doubles the amount of DNA originally present at the start of the cycle, thereby exponentially increasing the overall number of DNA copies. In theory, more than 1 million copies of the original DNA can be generated from as few as 20 cycles. Although this amplification technique is very sensitive and has tremendous application potential, it is not without problems. The powerful amplification procedure can yield false-positive results when samples are contaminated by nucleic acid left over from previously amplified DNA or by dead pathogens that exist in the sample. Other problems include primer artifact formation and nonspecific hybridization of primers to DNA samples. Several modifications to the original PCR technology have been made over the years to improve the sensitivity and application potential for PCR, including the use of multiple sets of amplification primers, multiplex PCR, PCR amplification of RNA by converting targeted RNA with reverse transcriptase to complementary DNA templates and real-time quantitative PCR. The cost-benefit ratio of PCR as compared with traditional microbiologic methods must be evaluated. Molecular amplification schemes such as PCR have become routine in situations in which rapid turnaround time is essential to improve patient diagnosis and outcome, for example, real-time universal screening for acute HIV infection and routine testing and monitoring of patients receiving treatment for HIV infection, and the isolation and detection of fastidious or slow-growing organisms such as *M tuberculosis*, *B burgdorferi*, and *Helicobacter pylori*. Another potential application for this technology is the early detection of multidrug-resistant organisms. Amplification of resistant gene markers would aid in rapid selection of the most appropriate therapy in the treatment of organisms in which days or weeks traditionally are required for culturing and determining basic susceptibility. Examples fitting this description include the rapid detection of isoniazid and rifampin gene markers for *M tuberculosis*, early detection of the *mecA* gene responsible for methicillin-resistance in *Staphylococcus aureus*, and identification of resistant genes responsible for production of β-lactamase capable of destroying specific cephalosporins and multidrug-resistant *H pylori*.[17–20]

EVALUATION OF ANTIMICROBIAL ACTIVITY AND DETERMINATION OF ANTIMICROBIAL PHARMACODYNAMICS

5 The laboratory evaluation of antimicrobial activity is an important component of the pharmacotherapeutic management of infectious diseases. The integration of this activity 6 with various pharmacokinetic properties of the antimicrobial agent determines the drug's pharmacodynamic characteristics. Antimicrobial pharmacodynamics have become a crucial consideration for the clinician for selecting both empirical and pathogen-directed therapy, formulary decision making, developing antimicrobial streamlining programs, and for intravenous-to-oral antimicrobial switch protocols.

5 Most antimicrobial susceptibility testing methods that are used in the clinical laboratory are well characterized and have been standardized by the Clinical and Laboratory Standards Institute (CLSI). However, controversies exist about which test methods provide the most useful information, how to report these results, and how to apply them to the treatment of patients.[21] Nevertheless, there are many investigations that show that the general antimicrobial susceptibility or resistance profile of an infecting organism correlates with clinical and/or microbiologic responses to therapy.

Most of the standardized and well-accepted test methods evaluate the susceptibility of aerobic, nonfastidious bacteria. However, substantial progress has been made to develop sensitive, specific, reproducible, and clinically useful susceptibility tests for anaerobic bacteria, yeasts, mycobacteria, and viruses. Continued advances in technology should further improve test methods and the rapidity with which the results can be applied to the management of patients. Although these newer systems are often expensive, the increased quality and decreased overall costs of patient care can determine their cost-effectiveness.

QUANTITATIVE ANTIMICROBIAL SUSCEPTIBILITY TESTING

MINIMAL INHIBITORY CONCENTRATIONS

5 The *minimal inhibitory concentration* (MIC) is defined as the lowest antimicrobial concentration that prevents visible growth of an organism after approximately 24 hours of incubation in a specified growth medium. The MIC quantitatively determines in vitro antibacterial activity. Classically, MICs were determined through the macrotube dilution method, which uses liquid growth medium (broth), doubling serial dilutions of antimicrobials in test tubes, and a standard inoculum of bacteria (approximately 10^5 colony-forming units [CFU]/mL). The tubes (up to 10 mL) were incubated at approximately 35°C (95°F) for 18 to 24 hours and then examined for visible bacterial growth (Fig. 113–3). Because macrodilution MIC testing is laborious and supply intensive, it is not used often in the contemporary clinical microbiology laboratory. However, one advantage of this method is that it tests a large inoculum of bacteria—a factor that can improve the detection of small numbers of resistant subpopulations or document the presence of inducible resistance.

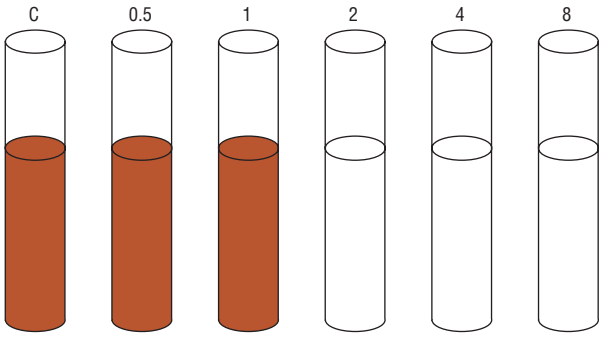

FIGURE 113-3. Macrotube minimal inhibitory concentration (MIC) determination. The growth control *(C)*, 0.5 mg/L, and 1 mg/L tubes are visibly turbid, indicating bacterial growth. The MIC is read as the first clear test tube (2 mg/L).

The use of 96-well microtiter plates substantially reduces the amount of growth medium and preparation time needed for broth-dilution MIC testing in the clinical laboratory. Volumes of 100 to 200 microliters (mcL) or less of medium are used, and multichannel pipets and/or automated systems allow efficient preparation of numerous tests (Fig. 113–4). The microdilution MIC test method is currently the most commonly used susceptibility test method in the clinical microbiology laboratory. Although microdilution MIC testing is a vast improvement over macrodilution MIC testing, it still has important shortcomings. These include both limitations in the numbers and various types of antimicrobials to use in the test (especially with premade or premanufactured trays) and a limited ability to detect some forms of antimicrobial resistance (e.g., β-lactamases in gram-negative bacteria).[22]

The MIC also can be determined using solid agar growth medium. For the agar dilution MICs, the test antimicrobial is added to the molten agar at the desired concentration just prior to its solidification. After the agar has hardened, suspensions of test bacteria are applied to the agar. As with broth MICs, the agar dilution MIC is defined as the lowest concentration that prevents the visible growth of the organism after an overnight incubation period. The primary advantages of the agar dilution MICs are the ability to test many bacteria on the same agar plate and the flexibility to choose specific antimicrobials. These advantages often are outweighed by the need to prepare agar plates manually and the instability of the antimicrobial in the agar as compared with commercially prepared microtiter MIC trays. Although agar dilution MIC once was considered the standard susceptibility test for many bacteria and for certain slow-growing organisms such as *M tuberculosis*, its use has declined in most clinical laboratories with the advent of more rapidly performed and less cumbersome susceptibility testing methods (e.g., microtiter MICs, PCR, radiometric, and/or fluorometric tests).

LIMITATIONS AND PROBLEMS WITH MIC TESTING

5 Some of the limitations and problems of MIC testing are academic in nature, whereas others can have important implications for the management of patients with serious infections. For example, because the MIC only represents the concentration of antimicrobial that is needed to inhibit visual growth of the most resistant cells within the tested bacterial population, there can be a small percentage of bacteria present within the large numbers at the site of infection that are more antimicrobial-resistant than the MIC would indicate. Use of the antimicrobial then could select these more resistant subpopulations, resulting in poor clinical response. This phenomenon can be observed with intermediate vancomycin resistance in *S aureus*, as well as in strains of gram-negative bacteria such as the *Enterobacteriaceae* species that produce both plasmid-borne and chromosomal β-lactamases.[22,23]

Many other factors also can influence the in vitro MIC value obtained and its subsequent application to the in vivo situation. The bacterial growth medium used and cation content can affect the activity of many drugs significantly. For example, aminoglycosides are more active against *P aeruginosa* in a medium supplemented with physiologic concentrations of magnesium and calcium (CLSI standardized method) than in a medium without these cations. MIC values of antibiotics that are highly bound to plasma proteins are significantly higher when the test medium contains human serum. As testing of these drugs in a serum-supplemented medium has not gained widespread acceptance, their in vivo activity can be overestimated by in vitro MIC test results. Fortunately, the standardized guidelines for testing and quality assurance procedures proposed by the CLSI attempt to minimize the impact of these problems and are followed by most clinical and research laboratories.[24] However, when a patient infected with an apparently susceptible organism fails therapy, it is important for the clinician to consider these potential confounding factors as possibly being related to the observed failure. In such situations, consideration of antimicrobial pharmacokinetics and pharmacodynamics also often can help to better predict therapeutic response as compared with organism susceptibility alone.

FIGURE 113-4. Depiction of a 96-well microtiter plate with minimal inhibitory concentration (MIC) assays for antibiotics used commonly against gram-negative pathogens. The shaded wells indicate visible bacterial growth. The MICs (milligrams per liter) for this organism would be 16 for piperacillin, 4 for aztreonam, 2 for ceftazidime and cefepime, 1 for meropenem, 0.5 for ciprofloxacin and gentamicin, and 0.25 for tobramycin. GC is the growth control (no antibiotic added).

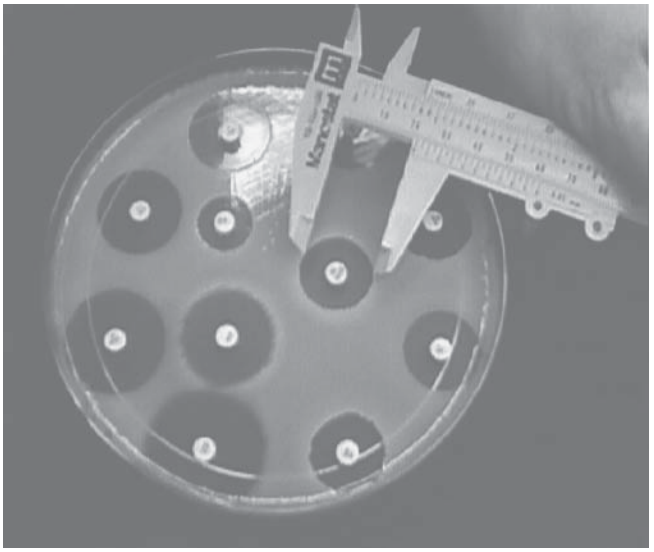

FIGURE 113-5. Disk diffusion susceptibility test. Antibiotic-impregnated disks are placed on the surface of a plate previously inoculated with the test organism. The plate is incubated for 18 hours, and the subsequent zones of inhibition are measured. The zone size correlates with the sensitivity of the organism. The larger the zone, the more sensitive is the organism to the specific antibiotic. On the basis of predetermined zone breakpoints, organisms can be classified as susceptible, resistant, or intermediately susceptible to the antibiotic. *(Photograph courtesy of the Anti-Infective Research Laboratory, Wayne State University, Detroit, MI.)*

QUALITATIVE ANTIMICROBIAL SUSCEPTIBILITY TEST METHODS

DISK DIFFUSION ASSAY

The disk diffusion assay method for susceptibility testing (Kirby-Bauer method) was developed in the 1960s by Bauer and coworkers as a way to reduce the labor needed for tube dilution susceptibility testing.[25] It still remains one of the more common susceptibility test methods used in the clinical microbiology laboratory owing to its high degree of standardization, reliability, flexibility, low cost, and simplicity of test interpretation. Up to 12 user-selected antibiotic-impregnated paper disks are placed on an agar plate previously streaked with a standard suspension of bacteria ($1–2 \times 10^8$ CFU/mL). The drug contained in the disk diffuses in a concentration gradient out into the agar. The plate is incubated (18 to 24 hours at 35°C), and visual bacterial growth occurs only in areas in which the drug concentrations are below those required for growth inhibition. The diameters of the zones of inhibition are measured via calipers or automated scanners and are compared with standard zone size ranges that determine susceptibility, intermediate susceptibility, or resistance to the antimicrobials that were tested (Fig. 113–5). Although factors such as agar composition, incubation temperature, bacterial inoculum, and antibiotic paper disk composition can influence results, the standards for testing conditions and interpretive zone sizes are well defined by the CLSI.

QUALITATIVE VERSUS QUANTITATIVE SUSCEPTIBILITY TESTING OF MICROORGANISMS

Quantitative MIC data often are reported to the clinician qualitatively by deeming an organism "susceptible," "intermediate or indeterminate" or "moderately susceptible," or "resistant" to a given antimicrobial agent. Many factors are considered to determine these qualitative susceptibility classifications (also referred to as "breakpoints" for the antibiotic). These include pharmacokinetic properties, the distribution of MICs for the organisms, and the clinical and bacteriologic responses observed for the antimicrobial against strains of bacteria with various MIC values. This simplification makes the susceptibility data easily interpretable by non–infectious disease clinicians. Pathogens classified as susceptible to an antibiotic are those with the lowest MICs, and they are the most likely to be eradicated during therapy of infections using typical drug doses. Conversely, resistant organisms are bacteria with significantly higher MICs that, when treated with the antimicrobial, will result in a less-than-optimal clinical response, even at the highest doses. The indeterminate classification exists when the number of strains with MICs in the given range is too small to derive robust conclusions on susceptibility or resistance to the antimicrobial. Responses to therapy for organisms that are moderately susceptible/intermediately susceptible/indeterminate can be variable. These organisms can respond to treatment with maximal doses of the antimicrobial or can respond when the drug is known to be concentrated at the site of infection (e.g., urinary tract infections treated by drugs excreted by the kidneys).

There are concerns that the "user friendly" susceptible/resistant classification system can oversimplify the decision-making process for treating infections. For example, a critically ill patient may not respond to the antimicrobial therapy of a susceptible organism at the usual doses. If serum concentrations or concentrations at the site of infection could be assayed (not practically done), one might discover suboptimal concentrations as a result of inadequate tissue perfusion. Likewise, a patient with severe vascular insufficiency and a diabetic foot infection may fail a course of therapy with normal doses of an antimicrobial and a susceptible organism because of inadequate drug delivery. Additionally, some investigators have shown that different outcomes can be achieved for "susceptible" organisms with different MIC values[26] and also that substantial (although not clinically acceptable) clinical and/or microbiologic cure rates can occur for infections that are caused by resistant organisms.[27] These reports emphasize that in vitro susceptibility does not correlate unequivocally with clinical success and that resistant organisms do not always equate with impending clinical failure.

CLINICAL CONTROVERSY

Some clinicians believe that the MICs for all antimicrobials for which susceptibility testing was performed should be reported to allow for the most appropriate antimicrobial selection for the patient. However, others believe that only selective antimicrobial susceptibility should be reported to avoid overprescribing of more costly broad spectrum antimicrobials.

Similarities in the spectrum of activity for classes of antibiotics have led to the concept of *class testing*. Thus cephalothin susceptibility results are extrapolated to other first-generation cephalosporins, such as cephalexin or cefazolin. Likewise, susceptibility to an antibiotic that typically has minimal activity usually ensures that other more potent agents in its class will have activity as well. However, many gram-negative organisms have now developed extended-spectrum β-lactamases (ESBLs) that often have different activity against members of the same drug class. These developments significantly limit the utility of class testing to reduce susceptibility testing workload.

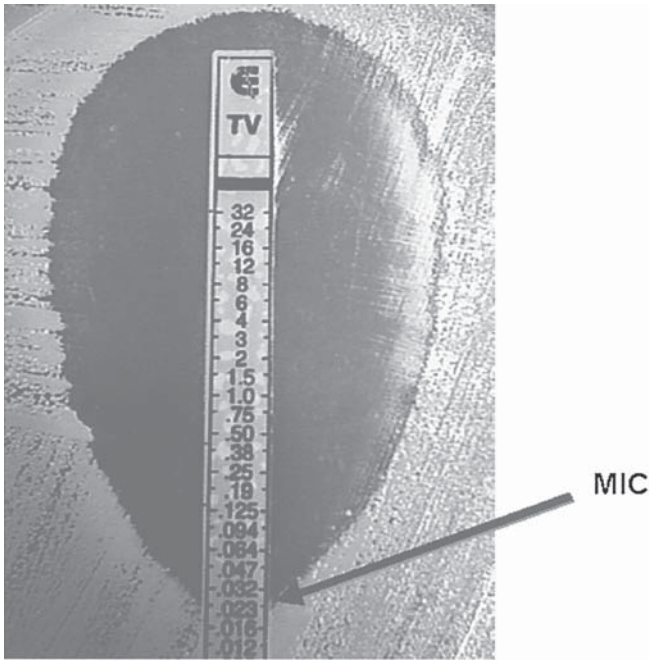

FIGURE 113-6. Photograph of E test susceptibility strip. The minimal inhibitory concentration (MIC) is determined from the point where the zone of inhibition intersects with the numerical scale. *(Photograph courtesy of the Anti-Infective Research Laboratory, Wayne State University, Detroit, MI.)*

OTHER SUSCEPTIBILITY TESTS

EPSILOMETER TEST

8 The Epsilometer test (Etest; AB bioMérieux, Nouvelle, France) combines the benefits of quantitative MIC test methods with the ease of agar diffusion testing. The Etest is a plastic strip impregnated with a known, prefixed concentration gradient of antibiotic that is placed on an agar plate streaked with a suspension of known bacterial inoculum. The drug instantly diffuses from the plastic strip to form an effective concentration gradient within the agar. After overnight incubation, elliptical zones of inhibition are formed; the point where the bottom of the ellipse crosses the plastic strip is correlated with an MIC value printed on the strip (Fig. 113–6). A similar product (M.I.C. Evaluator; Oxoid Limited, Hampshire, United Kingdom) is also available. Many investigators have analyzed the Etest's correlation with standard susceptibility methods and assessed its potential clinical use. In general, values obtained with Etest methods are comparable with or even more consistent and accurate than standard methods. In fact, the Etest method is the recommended method for susceptibility testing of *Streptococcus pneumoniae*. However, the widespread clinical use of the Etest has been limited primarily by the excessive costs of the test strips (nearly 10 times more costly than antibiotic-impregnated disks) in relation to the benefits that may be gained from their use.

AUTOMATED ANTIMICROBIAL SUSCEPTIBILITY TESTING

8 Various degrees of automation have been applied to susceptibility testing. Early advances included automated preparation of microtiter trays, instrument-assisted readers, and computer-assisted result databases. Rapid automated susceptibility tests became available in the 1980s, and their use has increased substantially in the two subsequent decades. These systems often incorporate microprocessors, robotics, and microcomputers to rapidly identify organisms and produce susceptibility test results in as few as 3 hours.

There are three rapid automated susceptibility test systems in common use in clinical microbiology laboratories. The Vitek system (bioMerieux, Durham, NC) uses small plastic reagent "cards" that contain 64 microwells for the testing of various antimicrobials or indicator chemicals. Bacterial test suspensions enter the wells by capillary diffusion, and growth is monitored automatically via photometric assessment of turbidity every hour for up to 15 hours. When the growth control reaches a specified turbidity level, growth curves for all wells are calculated and compared with the growth control curve for slope normalization. Computerized linear regression and the use of best-fit line coefficients produce an algorithm-derived MIC. The clinical laboratory can control the result output that is generated (qualitative susceptibility, quantitative susceptibility, or both).

The Microscan Walkaway system (Siemens Healthcare Diagnostics, Deerfield, IL) is a rapid test system that uses fluorogenic substrate hydrolysis as an indicator of bacterial growth. This system uses standard microdilution test trays and a computer-controlled incubator and reader unit that can perform robotic manipulations, such as reagent addition and tray rotation, to allow for spectrophotometric or fluorometric growth assessments. As with the Vitek system, growth curves are generated, and algorithms applied for the determination of MICs; output is via computer or video display.

The final system is the BD Phoenix Automated Microbiology System (BD Diagnostics, Sparks, MD). This system utilizes an oxidation-reduction detector and a turbidometric growth detection system to determine antibiotic resistance/susceptibility. Output of data is similar to the other two automated systems previously described.

8 The results obtained from all of these three systems generally are comparable. However, there have been documented differences in the ability of these systems to accurately detect emerging resistance mechanisms such as vancomycin resistance in Staphylococci and carbapenem resistance in gram-negative pathogens.[28,29] Importantly, all of the systems contain information management software that allow for the storage and rapid retrieval of historical susceptibility data. They can produce chartable patient data reports, antibiograms (summaries of overall resistance for organisms causing infections in a given hospital), and epidemiologic reports. These systems also can be interfaced with other clinical information systems, such as the pharmacy, infection control, or other laboratory data systems, which can help to improve clinical outcomes.[30]

ADVANCES IN SUSCEPTIBILITY TESTING FOR MYCOBACTERIA, FUNGI, AND VIRUSES

Impressive advances have been made in the past decade in the areas of mycobacterial, fungal, and viral susceptibility testing. The use of radio-metric techniques, such as the BACTEC TB460 system (Becton Dickinson Biosciences, Sparks, MD), has revolutionized the analysis of antimicrobial susceptibility for *M tuberculosis* and other slow-growing mycobacteria.[31] Radiometric susceptibility testing involves the incubation of *M tuberculosis* in liquid medium containing carbon-14 (^{14}C)-labeled growth substrate. As organisms grow, respiration causes the release of ^{14}C, which is then detected. The growth indices for antimicrobial-containing bottles are compared with those of a control bottle with the calculation of an MIC. Use of this method, when coupled with the rapid processing of samples, can reduce the time to susceptibility result generation to approximately 1 week. A newer mycobacterial susceptibility

testing method (the BACTEC Mycobacteria Growth Indicator Tube [MGIT 960]; Becton Dickinson Diagnostic Instruments, Sparks, MD) that is fully automated and that employs detection of fluorescence related to growth also has been developed. It produces results in a similar time frame and with similar reliability as the radiometric method.[32] Primary advantages of this system are its automation, the elimination of radioactivity, and the elimination of needle use. Although the slower agar proportion susceptibility method (generating results in approximately 1 month) is still considered the reference standard for mycobacterial susceptibility testing by the CLSI, the group now recommends the use of a rapid susceptibility testing method to ensure that the Centers for Disease Control and Prevention (CDC) guidelines for reporting susceptibility results for *M tuberculosis* infections within 28 days of specimen receipt in the laboratory can be met.[33] In the future, the use of molecular probes for mycobacterial resistance genes most likely will become a more important component of mycobacterial susceptibility determinations, especially in light of the increasing problems with antimicrobial resistance.[34]

There has been a substantial increase in the prevalence of fungal infections in the past two decades and an increase in the development and use of antifungal agents has followed. Historically, antifungal susceptibility testing was imprecise and fraught with many inconsistencies. However, pioneering research in the past decade has resulted in the development of CLSI guidelines for the antifungal susceptibility testing methods of both yeasts and filamentous fungi (molds).[35,36] Use of these techniques can result in greater than 90% inter- and intralaboratory reproducibility. Although routine antifungal testing of every isolate is not generally necessary for most clinical microbiology laboratories, periodic batch testing for the development of antibiograms and for the surveillance of resistance and/or antifungal testing of patients with such infections as cryptococcal meningitis or oropharyngeal candidiasis refractory to therapy are warranted.

DETECTION OF RESISTANCE FACTORS

There are a number of methods in use that directly detect the production of antimicrobial resistance in pathogens. β-Lactamase production can be detected rapidly and easily in the clinical laboratory with the use of nitrocephin disks. Nitrocephin is a chromogenic cephalosporin derivative that changes color on hydrolysis by β-lactamase. Colonies from a growing bacterial culture can be touched to a disk, with β-lactamase production noted within a few minutes. Although rapid and reliable, this method is limited to the assessment of strains of staphylococci, enterococci, *H influenzae, Moraxella catarrhalis*, and *N gonorrhoeae*. The nitrocephin disk also cannot detect β-lactam resistance caused by altered penicillin-binding proteins or by some of the newer ESBLs. The use of PCR or DNA probes for detection of β-lactamases improves sensitivity/specificity but is still limited to the research setting. In the years to come, these molecular biologic techniques should become more refined and more prominent in the clinical microbiology laboratory.

PCR has now become a standard method to quantify the replication of the HIV and hepatitis viruses in infected patients (the *viral load*, described as copies per milliliter).[37] Similar methods are used to determine the presence of genetic mutations in the HIV that are associated with increased resistance to one or more of the many antiretroviral medications available for clinical use. The use of these genotyping methods as an aid to select an optimized antiretroviral regimen has been correlated with an improved clinical response to therapy, as well as with a more potent reduction in the viral load.[37]

The detection of methicillin resistance in *Staphylococcus* (methicillin-resistant *S aureus* [MRSA]) is crucial to ensure appropriate therapy. Methicillin resistance is the result of the *mecA* gene, which encodes for an altered penicillin-binding protein (penicillin-binding protein 2a) that has a low binding affinity for β-lactams. It is particularly difficult to detect this resistance, although, because of the heterogeneous expression of the phenotype—it is common for only 1 in 10^{4-6} tested bacterial cells to express methicillin resistance (even though all cells may have the genetic ability to do so). Screening via oxacillin disks or by oxacillin-containing agar (6 mcg/mL) was once considered the gold standard for resistance detection prior to the development of PCR and DNA probes that were specific for *mecA*. The *mecA* PCR test is available for clinical use, is 99% sensitive and specific, and allows for the rapid (within 6 hours) determination of the presence of methicillin resistance. Although the *mecA* PCR test has been available for many years, many laboratories do not use it commonly because of its high cost relative to other screening methods with acceptable sensitivity/specificity. For example, the presence of MRSA in a nasal swab or a blood culture sample can now be determined directly and rapidly within 24 hours using chromogenic technology (CHROMagar MRSA). This technology uses chromogenic substrates and a cephalosporin; MRSA strains will grow in the presence of cephalosporins such as cefoxitin and will produce mauve-colored colonies resulting from hydrolysis of the chromogenic substrates. The sensitivity and specificity for this test is as high as 97% and 99%, respectively.[38,39] In addition, fluorescence in situ hybridization (FISH) is a novel technique that uses peptide nucleic acid probes to target ribosomal RNA (rRNA) to rapidly identify both bacteria and yeasts in culture. Peptide nucleic acid probes that specifically target 16S rRNA of *S aureus* have now been developed for rapid and specific identification of *S aureus* directly from blood cultures that are gram-stain positive for gram-positive cocci. The assay has 100% sensitivity and 96% specificity.[40]

The detection of decreased vancomycin susceptibility in gram-positive organisms has become more important with the increased prevalence of both vancomycin-resistant Enterococcus (VRE) and vancomycin-intermediate-resistant and vancomycin-resistant *S aureus* (VISA and VRSA). The vancomycin agar screening method (Brain-Heart Infusion agar containing 6 mg/L of vancomycin) is an inexpensive and reliable way to detect vancomycin resistance. With this test, the growth of any colonies from a sample of the test organism (10^5–10^6 CFU) after 24 hours of incubation would indicate the presence of decreased vancomycin susceptibility (VISA) or vancomycin resistance (VRE, VRSA) within the test strain. This screening method appears to work well for VRE, but it appears to be less reliable for detecting VISA or VRSA strains when compared to the CLSI broth microdilution reference method.[28] It is important to note that most of the MIC testing methods currently used in the clinical microbiology laboratory do appear to reliably detect these VISA and VRSA strains.[28]

SPECIAL IN VITRO TESTS OF ANTIMICROBIAL ACTIVITY

MINIMAL BACTERICIDAL CONCENTRATION

9 In certain infections (e.g., Gram-positive bacterial meningitis and endocarditis), the bactericidal (killing) activity may be more predictive of a favorable infection outcome than the MIC.[41] The minimal bactericidal concentration (MBC) can be performed in conjunction with the broth microtiter MIC test by taking aliquots of broth from microtiter wells that demonstrate no visible growth and plating the samples onto antibiotic-free agar plates for subsequent incubation. The MBC is defined as the lowest concentration of drug that kills 99.9% of the total initially viable cells (representing a 3 $\log_{10}$ CFU/mL or greater reduction in the starting inoculum).

For certain antibiotic classes such as the aminoglycosides and the quinolones, the MIC often approximates the MBC. However, for β-lactam antibiotics and glycopeptides, the MBC can exceed the MIC substantially, resulting in an overestimation of in vivo bactericidal activity. When the MBC exceeds the MIC by 32-fold or more, an organism is said to be *tolerant* to the antimicrobial's killing activity. Although the phenomenon of tolerance has been documented for β-lactams and glycopeptides against certain staphylococci, streptococci, and enterococci, its impact on the outcome of infections caused by organisms other than those just mentioned appears to be limited.

TIMED-KILL CURVE TESTS

Timed-kill curve tests are not performed routinely in the clinical laboratory but can provide important additional data on the effects of an antimicrobial on bacteria. For timed-kill curve tests, a standard inoculum of bacteria (10^6 CFU/mL) is placed in a test tube containing liquid growth medium with or without desired test concentrations of antimicrobial. Samples are removed periodically to determine the number of living cells at the given time points. The viable cell counts are plotted versus time to construct the timed-kill profile of the antimicrobial. The tested concentration of antimicrobial is considered to be bactericidal if it causes at least a 3 $\log_{10}$ CFU/mL reduction in viable inoculum. Comparisons of the relative rates of bacterial killing also can be performed in timed-kill curve experiments. Additionally, the presence of concentration-dependent killing activity (where killing increases with increasing drug concentrations above the MIC) versus concentration-independent killing activity can be determined from a timed-kill curve experiment. An example of results from a timed-kill curve experiment is depicted in Figure 113–7. These data can help to predict the best way to administer an antimicrobial to maximize activity. For example, lower-dose, more frequent (or continuous) infusions would be preferable for concentration-independent antibiotics, while higher-dose intermittent administrations would maximize activity for concentration-dependent antibiotics.

POSTANTIBIOTIC EFFECT

The *postantibiotic effect* (PAE) is defined as the persistent suppression of an organism's growth after a brief exposure to an antibiotic.[42] A PAE experiment is performed by exposing a fixed inoculum of organism to a set concentration of antibiotic (typically some multiple of the MIC) (Fig. 113–8). The antibiotic is then removed either by inactivation (e.g., inactivation by a β-lactamase or binding the antibiotic to a resin) or by filtration/centrifugation of the mixture. The cells are resuspended in antibiotic-free growth medium, and samples are removed frequently (every 0.5 to 2 hours) to determine resumption of normal growth. The PAE is quantified as the difference in time that it takes the organism exposed to the antibiotic to demonstrate a 10-fold increase in viable cells per milliliter as compared with a separate culture of organism not subjected to the antibiotic. A PAE equal to or greater than 1 hour has been demonstrated for most antibiotics against gram-positive bacteria (β-lactams, vancomycin, daptomycin, linezolid, telavancin). As a general rule, antibiotics that inhibit DNA or protein synthesis (e.g., quinolones and aminoglycosides) demonstrate significant PAEs against gram-negative organisms. An exception to this rule are the carbapenem cell wall synthesis inhibitors (e.g., ertapenem, imipenem, and meropenem), which demonstrate PAEs against selected strains of gram-negative organisms. The primary clinical application of the PAE is to allow for less frequent administration of antimicrobials while still maintaining adequate antibacterial activity (e.g., extended-interval aminoglycoside administration).[43]

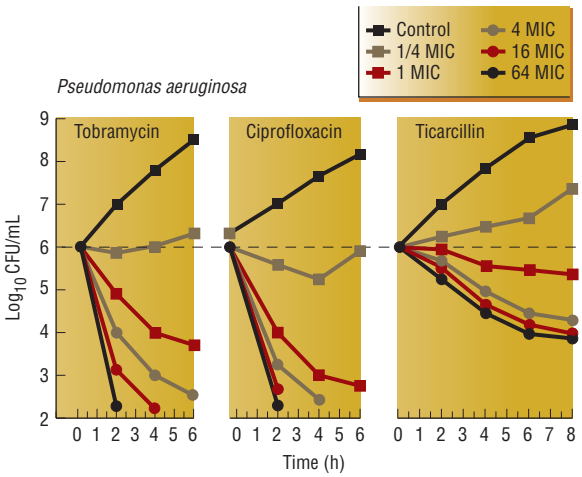

FIGURE 113-7. Killing curve depicting the effect of concentration on antibiotic bactericidal activity. (CFU, colony-forming unit; MIC, minimal inhibitory concentration [0.25-64 times the MIC; the organism tested was *P aeruginosa* ATCC 27853]) *(From Craig WA, Ebert SC. Killing and regrowth of bacteria in vitro: a review. Scand J Infect Dis Suppl 1991;74:63–70).*

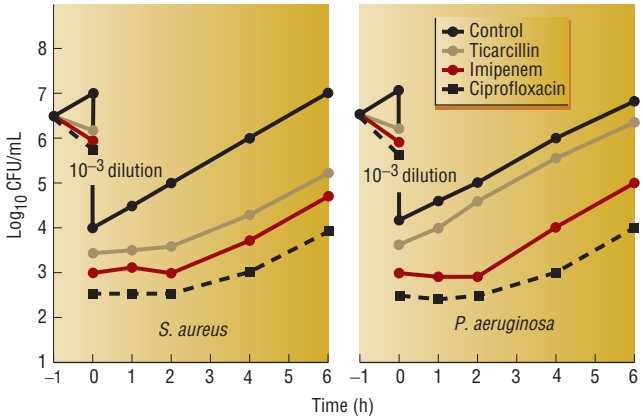

FIGURE 113-8. Postantibiotic effect. In this experiment, fixed inocula of *Staphylococcus aureus* and *Pseudomonas aeruginosa* are exposed to ticarcillin, imipenem, and ciprofloxacin at a set concentration of four times the MIC. The organism and the antibiotic are then diluted 1,000-fold to a point where the antibiotic concentration is far below the MIC of the organism. Growth suppression of *S aureus* following exposure to the three drugs (postantibiotic effect [PAE]) occurs for approximately 2 hours. Growth suppression of *P aeruginosa*, however, is only demonstrated for imipenem and ciprofloxacin. The ß-lactam ticarcillin has no effect on the growth of *P aeruginosa*. (CFU, colony-forming unit; MIC, minimal inhibitory concentration.) *(From Craig WA, Ebert SC. Killing and regrowth of bacteria in vitro: a review. Scand J Infect Dis Suppl 1991;74:63–70)*

ANTIMICROBIAL COMBINATION EFFECT TEST

Antimicrobial combination therapy is used frequently to treat serious infections. Combination therapy can be used prior to knowing the pathogen or antibiotic susceptibility for the treatment of infections in neutropenic patients and in patients with enterococcal endocarditis or bacteremia, sepsis, or pneumonia caused by *P aeruginosa*. In these cases, it is important to know whether the combination will have beneficial (or detrimental) effects on the overall antibacterial activity of the regimen. For example, the combination can result in activity that is significantly greater than the sum of activity of either agent alone (i.e., synergy). Conversely, the combination can result in activity that is worse than either agent alone (i.e., antagonism). Combination activity that is neither synergistic nor antagonistic is said to be *indifferent* or *additive*.[44]

Two methods are used to determine the expected effects of combination antibiotic therapy. For the most part, both methods are not used commonly in the clinical microbiology laboratory owing to the substantial labor involved with these tests and the lack of strong correlation with clinical outcome in the majority of infections. The first method is the microtiter fractional inhibitory concentration (FIC, or "checkerboard" method). The FIC is performed in a similar manner to the microtiter broth MIC except that two antibiotics are tested in the same microtiter plate. Twofold serial dilutions of one antibiotic are made in one direction on the plate (e.g., from right to left), whereas dilutions of the second antibiotic are made from the other direction on the same plate (e.g., from top to bottom). This method produces all possible combinations of 2-fold concentrations for the two drugs being tested. An inoculum of test bacteria is added to all wells, and the results are read in a similar manner as the MIC test. The FIC is expressed mathematically by calculation of the FIC index. The FIC index is calculated as

$$\text{FIC index} = \frac{A}{\text{MIC}_A} + \frac{B}{\text{MIC}_B}$$

where A or B is the lowest concentration of the drug that is inhibitory in the presence of the second drug, and the MIC is the minimal inhibitory concentration of each drug tested alone. Synergism is defined as an FIC index of 0.5 or less, indifference is defined as an FIC index of between 0.6 and 4.0, and antagonism is defined as an FIC index of greater than 4.0.[44] The microtiter FIC methods have been adapted to allow the use of Etest antibiotic-susceptibility test strips.[45] In this method, two antibiotic Etest strips are crossed at the individual MIC of each antibiotic; an extension of the zone of inhibition beyond that from either antibiotic alone is considered additive or synergistic activity, and an FIC index can be calculated in a similar manner as the microtiter method.

The second most common method to determine the effects of antibiotic combinations is an adaptation of timed-kill curve tests. Two antibiotics are added to the same test tube at fixed concentration fractions of the MIC for each drug, and killing is quantified. With this method, synergism is defined as a 100-fold decrease in viable organisms at 24 hours for the combination as compared with the most potent antibiotic tested alone. Antagonism is defined as a 100-fold or greater increase in viable organism count[44] (Fig. 113–9). It is important to note that although antagonism has been demonstrated for several combinations in vitro (e.g., penicillin plus tetracycline, chloramphenicol and an aminoglycoside, fluoroquinolones and rifampin), antagonism in vivo has been demonstrated only infrequently.

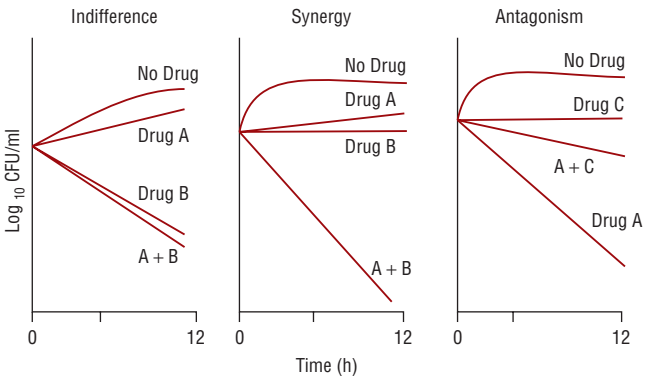

FIGURE 113-9. Timed-kill curve illustrating indifference, synergy, and antagonism. (CFU, colony-forming unit.)

Although the methods for testing the effects of antimicrobial combinations are well described, the results from these tests have not been adequately studied in the context of many infection outcomes. There is little debate that the combination of a β-lactam antibiotic and an aminoglycoside is required for successful treatment of enterococcal endocarditis. For enterococci, susceptibility to high concentrations of aminoglycosides (e.g., gentamicin, 500 mg/mL) is evaluated in the clinical laboratory because it correlates closely with synergy when the drug is combined with β-lactam antibiotics.

The concept of combination therapy is not universally accepted for the treatment of other infections. There is ongoing debate as to whether the combination of a broad-spectrum β-lactam and an aminoglycoside is needed (versus the β-lactam alone) for the therapy of such infections as gram-negative bloodstream infections or infections in neutropenic patients. In individual studies, combination therapy has resulted in improved outcomes in patients with severe illness and in patients with *P aeruginosa* bloodstream infections, but pooled meta-analyses have disputed these results.[46]

LABORATORY MONITORING OF ANTIMICROBIAL THERAPY

⑩ The clinician should have an understanding of in vivo antimicrobial agent disposition to select the most appropriate therapy for a given infection and to help monitor for clinical or bacteriologic efficacy. Serum concentration monitoring is the most common method used to attempt to maximize efficacy and minimize toxicity of antimicrobials. Because most antimicrobials are well tolerated at their usual doses, only a select few agents (e.g., aminoglycosides, chloramphenicol, and vancomycin) are monitored routinely in the current clinical environment. There are a number of direct and indirect methods that are used to quantify the concentration of antimicrobial in an experimental sample.

METHODS OF ANTIMICROBIAL CONCENTRATION DETERMINATION IN CLINICAL SAMPLES

Fluorescence-Polarization Immunoassay

The fluorescence-polarization immunoassay (FPIA) technique involves the application of the principles of fluorescence when molecules are exposed to light. A fluorescein-labeled drug and antibody that is directed against the drug are added in constant amounts to samples with unknown drug concentrations and to concentration standards. When the fluorescein-labeled drug complexes with the antibody, a quantifiable change in the fluorescence polarization occurs. When a sample containing non–fluorescein-labeled drug (i.e., a patient's serum sample) is mixed with the standard mixture, competition for antibody binding occurs. Comparison of the change caused by the patient's sample to the changes caused by standard concentrations determines the specific drug concentration in the patient sample.

FPIA is the most commonly used assay method for the determination of aminoglycoside and vancomycin serum concentrations in the clinical laboratory setting. Advantages of this technique include its automation, and the disadvantages include the expenses for reagents and the cost for the purchase of the automated system.

Radioimmunoassay

Radioimmunoassay (RIA) uses a radiolabeled drug and an antibody directed against the specific drug to determine the concentration

contained in an unknown sample. The theory behind the assay is similar to FPIA because radiolabeled antibiotic and unlabeled antibiotic (in the patient's serum sample) are equilibrated with the antibody. The amount of free radiolabeled drug is measured and compared with the values obtained with standard concentrations of the radiolabeled drug alone to determine the concentration in the patient sample. Although RIA has good sensitivity and specificity, its main disadvantage compared with FPIA is the expense and hassle of handling and disposal of the radioactive waste generated during the test.

High-Pressure Liquid Chromatography

High-performance liquid chromatography (HPLC) permits the separation of different molecular species by passing a mobile solvent phase over a stationary phase. Drugs with a polarity similar to that of the stationary phase are retained for a time on the chromatographic column and then released after various retention times. Detection can be accomplished via fluorescence, electrochemical, or radiometric methods. The detector signal is proportional to the amount of molecules present. Standard curves are generated from known concentrations of the drug (usually recorded as peak area or peak height). Advantages of HPLC include a rapid turnaround time, precision, and an ability to detect the test drug in the presence of its metabolites and/or other drugs. Disadvantages include the high cost of HPLC instruments and the expertise required to perform the assays. These disadvantages usually relegate HPLC drug assay to the experimental and/or research settings.

Microbiologic Assay

Microbioassay of antimicrobial agents can be performed by several methods. The most common method is a modification of the disk diffusion antimicrobial-susceptibility technique. Typically, paper disks are placed on agar that contains an inoculum of a bacterium known to be highly susceptible to the antimicrobial agent to be assayed. Fixed volumes (usually 10 mcL) of a range of prepared concentration standards of the test drug are placed on the disks. The zones of growth inhibition are measured and plotted versus the drug concentration to generate a standard curve. Zone sizes from samples containing the unknown concentrations of the test drug are measured, and the concentrations are determined from the plotted curve; the drug concentration in unknown samples is determined from the standard curve generated from the known concentrations of the drug. The advantages of this method include its relative ease of performance and the minimal cost for equipment. The disadvantages of this method include interference from other antibiotics that can be present in the unknown sample, a lack of sensitivity/specificity for certain antimicrobials, and a slow turnaround time (usually 24 to 48 hours) for generation of results.

TIMING OF COLLECTION OF SERUM SAMPLES

⑩ Peak and/or trough concentrations are monitored routinely for only a select few antimicrobials (e.g., aminoglycosides and vancomycin) during the contemporary management of infections. It is crucial for the healthcare team to ensure that the antimicrobial's administration time and serum sample time(s) are meticulously recorded because even small errors in recording these (e.g., 1 hour) can have a substantial impact on the calculation of pharmacokinetics for antibiotics such as the aminoglycosides, which have relatively short elimination half-lives.

⑪ Samples ideally should be obtained after steady state is achieved (usually defined as the passage of at least 3 to 4 anticipated half-lives), but in certain situations, this may not be possible (e.g., critically ill patients with fluctuations in drug elimination owing to fluctuating hemodynamics, kidney function, and/or liver function). Generally, the timing of the peak serum sample collection is usually more critical than the trough concentration because adequate time must elapse to allow for completion of the distribution phase and to avoid underestimating the drug's volume of distribution.

SPECIFIC AGENTS

The aminoglycosides (i.e., amikacin, gentamicin, and tobramycin) and vancomycin remain the most common agents for which serum concentrations are monitored. A summary of the recommendations for serum concentration monitoring of these agents is shown in Table 113–2.

Aminoglycosides

⑫ There are many studies that have linked serum aminoglycoside concentrations with clinical response and with the occurrence of nephrotoxicity. One of the classic investigations into the

TABLE 113-2 Suggested Therapeutic Serum Concentrations for Selected Antimicrobial Agents

Drug	Sample	Target Concentrations (mg/L)	Comments
Gentamicin, Tobramycin (traditional dosage regimens)	Peak (1 h after start of 15- to 45-min infusion)	<5	Urinary tract infections
		>5	Bacteremia
		>6	Bacterial pneumonia
		>12	Endocarditis caused by *Pseudomonas aeruginosa*
	Trough	<2–3	High trough concentrations are most likely a result of and not a cause of nephrotoxicity
Amikacin	Peak	>15	Urinary tract infections
		>20	Bacteremia
		>24	Bacterial pneumonia, other serious infections
	Trough	>9–10	See comments regarding trough gentamicin/tobramycin concentrations
Single daily dosage regimens[49]			
Gentamicin Netilmicin Tobramycin	8-h postdose (*mid-dose*)	1.5–6	Concentrations above this range associated with nephrotoxicity in one study with netilmicin
Vancomycin	Trough	15–20	Recent data suggest this higher trough range due to low lung penetration, potential for resistance and increasing vancomycin MICs/MBCs[50]

MIC, minimal inhibitory concentration; MBC, minimal bactericidal concentration.
Data from Nicolau et al.,[49] and Rybak et al.[51]

relationship between serum aminoglycoside activity and clinical outcome revealed that peak serum concentrations of at least 5 mcg/mL for gentamicin and tobramycin and at least 20 mcg/mL for amikacin were associated with a lower prevalence of clinical failure rates during the treatment of gram-negative bacteremia.[47] Although earlier studies suggested that trough concentrations exceeding 2 to 4 mcg/mL for gentamicin and tobramycin and 10 mcg/mL for amikacin predisposed patients to nephrotoxicity, other investigations indicated that the development of aminoglycoside-related ototoxicity and nephrotoxicity is more complex and also is associated with the total exposure to the aminoglycoside (as measured by the AUC) and/or the total duration of aminoglycoside therapy.[48] The specific recommended serum peak and trough concentrations for the various aminoglycosides are described in Table 113–2.

Newer regimens of high dose once-daily or extended-interval aminoglycoside administration have gained widespread acceptance for use in the clinical setting. These regimens exploit the pharmacodynamic properties of these agents (i.e., concentration-dependent bacterial killing and a substantial PAE) to maximize activity while also attempting to minimize drug nephrotoxicity by reducing the total aminoglycoside exposure time for the patient's kidneys. The doses employed for extended-interval treatment typically range from 5 to 7 mg/kg of lean body weight (administered every 24 to 48 hours), with the dose and/or interval adjusted based on renal function or observed mid-dose serum concentrations.[49] Many prospective studies have been performed to evaluate the safety and efficacy of once-daily aminoglycoside dosing, and most have revealed similar rates of efficacy and toxicity, or trends toward improved efficacy and reduced toxicity for once-daily dosage regimens as compared with traditional (thrice daily) regimens.

Traditional methods of aminoglycoside serum concentration monitoring (evaluating peak and trough serum concentrations) cannot be applied to extended-interval dosing because the serum concentrations 24 hours after a dose ideally should be undetectable. A mid-interval serum sample can be taken approximately 6 to 12 hours after the dose to allow for use of first-order pharmacokinetic equations.

CLINICAL CONTROVERSY

Some clinicians believe that there is sufficient clinical data to support widespread use of once-daily aminoglycoside dosing without determination of individual patient pharmacokinetics. However, there are some clinicians that believe that the data is incomplete and that patients should receive individualized pharmacokinetic assessments and dosage adjustments.

Vancomycin

13 The area under the concentration-time curve to MIC ratio (AUC/MIC) is the most likely parameter predicting efficacy as demonstrated by animal and limited human data.[50] Although intravenous vancomycin has been associated with oto- and nephrotoxicity in humans, most of these reports occurred with older, impure formulations of the drug, with extremely high concentrations uncommon with contemporary dosing regimens, or when vancomycin was combined with known nephrotoxic agents. Although serum peak and trough concentrations were previously recommended for monitoring vancomycin therapy, now, only the trough concentration is routinely monitored since vancomycin is not a concentration-dependent killing antibiotic.

Weight-based dosage regimens and/or nomogram-based dosage methods were developed to help minimize monitoring of serum concentrations for the vast majority of patients. Most of these methods of empirical vancomycin dosing resulted in trough concentrations between 5 and 10 mcg/mL. However, higher vancomycin trough concentrations are now believed to be needed because of its poor penetration into tissue such as the lung, the association of the emergence of vancomycin nonsusceptible strains for those patients for which trough serum concentrations were maintained below 10 mg/L and the trend toward an increased prevalence of strains of staphylococci with higher vancomycin MICs and/or MBCs. There is some animal data and limited clinical data that suggest that targeting an AUC/MIC of ≥400 may improve patient outcome in patients with Staphylococcus aureus infections. Consensus-review guidelines for the dosing and monitoring of vancomycin suggest that vancomycin trough concentrations should be considered as the most accurate and practical means for monitoring efficacy.[51] Trough serum concentrations should be maintained above 10 mg/L to avoid the emergence of resistance. A serum trough concentration of 15 to 20 mg/L is recommended for patients with serious infections such as complicated bacteremia endocarditis, meningitis, and hospital-acquired pneumonia caused by *S aureus*.[52] A target trough concentration of 15 to 20 mg/L should achieve an AUC/MIC of ≥400 when the *S aureus* vancomycin MIC is ≤1 mg/L. Although more data are needed, targeting these higher troughs may result in an increased risk of renal dysfunction in some patients.[51]

CLINICAL CONTROVERSY

Some clinicians believe that vancomycin should no longer be considered as the drug of first-choice for treatment of serious staphylococcal infections—even when it is administered to target the new, higher trough range of 15 to 20 mg/L. The desired target attainment of an AUC/MIC of ≥400 may not be achieved with conventional doses of vancomycin with *S aureus* exhibiting a vancomycin MIC of ≥2 mg/L.

INTEGRATING ORGANISM SUSCEPTIBILITY WITH SERUM CONCENTRATION DATA TO IMPROVE ANTIMICROBIAL THERAPY

7 14 We have advanced our understanding substantially of the importance of considering both antimicrobial pharmacokinetics and organism susceptibility when selecting therapy for the treatment of infections. Antimicrobial regimens should be selected and/or designed to maximize the probability that bacterial killing is optimized and that the probability of resistance is minimized. For example, the activity of antimicrobials such as the fluoroquinolones and the aminoglycosides can be maximized if the ratio of the peak serum concentration to the organism MIC (peak-to-MIC ratio) is greater than or equal to 10.[52] Similarly, the probability of clinical and/or microbiologic infection cure can be maximized if a fluoroquinolone is chosen that achieves an area under the curve (AUC)-to-MIC ratio of 100 to 125 or greater for gram-negative bacteria (e.g., *P aeruginosa*) and 30 to 40 or greater for gram-positive bacteria (e.g., *S pneumoniae*). The clinical application of these principles to aminoglycoside dosage regimen optimization is depicted in Figure 113–10. Although the maintenance of concentrations above the infecting organism's MIC (the time above the MIC) best predicts the clinical efficacy of the β-lactam antimicrobials, the AUC-to-MIC ratio also appears to be a strong predictor for treatment outcome for certain organisms and in certain clinical situations (e.g., vancomycin for staphylococcal infections).[51]

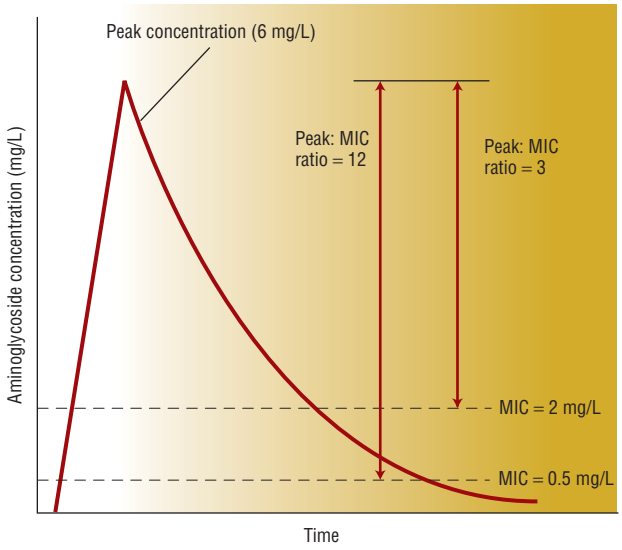

FIGURE 113-10. Illustration of the concept of peak concentration to the minimal inhibitory concentration (MIC) ratio for aminoglycosides. The MIC for the given organism to gentamicin is 2 mg/L, whereas the tobramycin MIC is 0.5 mg/L. Administration of gentamicin would result in a suboptimal peak:MIC ratio (<10), which could increase the chances for development of resistance or an inadequate response. Administration of tobramycin would result in a peak:MIC ratio of 12, which should improve efficacy. Note that modification of the gentamicin regimen to produce peak serum concentrations of 20 mg/L or more (as commonly done with once-daily administration) also would result in a peak:MIC ratio of ≥10.

Most of the data on optimization of antimicrobial pharmacodynamics have been generated in in vitro models of infection, in animal models of infection, within the context of controlled clinical trials, or through mathematical modeling of small data sets. However, research continues to emerge on the best ways to apply these valuable data to the everyday management of patients in the clinical setting. The recognition of the importance of antimicrobial pharmacodynamics already has resulted in such therapeutic innovations such as (1) the expansion of serum concentration monitoring for select antimicrobials (e.g., antiretroviral agents, antifungal agents), (2) suggested revisions of breakpoint values that define antimicrobial susceptibility and/or resistance, (3) development of nomograms or computer programs that can suggest optimal drugs and doses for a given infection, (4) novel administration methods such as prolonged infusion times for antibiotics such as β-lactams with time-dependent activity, and (5) the development of newer antimicrobial agents with minimized risks of suboptimal pharmacodynamics. These developments present exciting opportunities for healthcare providers to improve the outcomes of patients with infections in a variety of different healthcare settings.

ABBREVIATIONS

AIDS: acquired immunodeficiency syndrome
AUC: area under the curve
bDNA: branched DNA
CDC: Centers for Disease Control and Prevention
CLSI: Clinical and Laboratory Standards Institute
CFU: colony-forming unit
CMV: cytomegalovirus
CSF: cerebrospinal fluid
ELISA: enzyme-linked immunosorbent assay
ESBL: extended-spectrum β-lactamase
ESR: erythrocyte sedimentation rate
FIC: fractional inhibitory concentration
FISH: fluorescence in situ hybridization
FPIA: fluorescence-polarization immunoassay
HIV: human immunodeficiency virus
HPLC: high-performance liquid chromatography
KOH: potassium hydroxide
MBC: minimum bactericidal concentration
MHC: major histocompatibility complex
MIC: minimum inhibitory concentration
MRSA: methicillin-resistant *Staphylococcus aureus*
PAE: postantibiotic effect
PCR: polymerase chain reaction
PMN: polymorphonuclear leukocyte
RIA: radioimmunoassay
SBT: serum bactericidal titer
SIRS: systemic inflammatory response syndrome
SIT: serum inhibitory titer
TNF: tumor necrosis factor
VISA: vancomycin-intermediate *Staphylococcus aureus*
VRE: vancomycin-resistant enterococci
VRSA: vancomycin-resistant *Staphylococcus aureus*

CHAPTER 114

Antimicrobial Regimen Selection

DAVID S. BURGESS

KEY CONCEPTS

1. Every attempt should be made to obtain specimens for culture and sensitivity testing prior to initiating antibiotics.
2. Empirical antibiotic therapy should be based on knowledge of likely pathogens for the site of infection, information from patient history (e.g., recent hospitalizations, work-related exposure, travel, and pets), and local susceptibility.
3. Patients with delayed dermatologic reactions (i.e., rash) to penicillin generally can receive cephalosporins. Patients with type I hypersensitivity reactions (i.e., anaphylaxis) to penicillins should not receive cephalosporins. Alternatives to the cephalosporins include aztreonam, quinolones, sulfonamide antibiotics, or vancomycin based on type of coverage indicated.
4. Estimated creatinine clearance should be calculated for every patient who is to receive antibiotics and the antibiotic dose interval adjusted accordingly. Hepatic function should be considered for drugs eliminated through the hepatobiliary system, such as clindamycin, erythromycin, and metronidazole.
5. All concomitant drugs and nutritional supplements should be reviewed when an antibiotic is added to a patient's therapy to ensure drug–drug interactions will be avoided.
6. Combination antibiotic therapy may be indicated for polymicrobial infections (intra-abdominal, gynecologic infections), to produce synergistic killing (such as β-lactam plus aminoglycoside versus *Pseudomonas aeruginosa*), or to prevent the emergence of resistance.
7. All patients receiving antibiotics should be monitored for resolution of infectious signs and symptoms (e.g., decreasing temperature and white blood cell count) and adverse drug events.
8. Antibiotics with the narrowest effective spectrum of activity are preferred. Antibiotic route of administration should be evaluated daily, and conversion from intravenous to oral therapy should be attempted as signs of infection improve for patients with functioning gastrointestinal tracts (general exceptions are endocarditis and central nervous system infections).
9. Patients not responding to an appropriate antibiotic treatment in 2 to 3 days should be reevaluated to ensure (a) the correct diagnosis, (b) that therapeutic drug concentrations are being achieved, (c) that the patient is not immunosuppressed, (d) that the patient does not have isolated infection (i.e., abscess, foreign body), or (e) that resistance has not developed.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Choosing an antimicrobial agent to treat an infection is far more complicated than matching a drug to a known or suspected pathogen.[1,2] Most clinicians generally follow a systematic approach to select an antimicrobial regimen (Table 114–1). Problems arise when this systematic approach is replaced by prescribing broad-spectrum therapy to cover as many organisms as possible. Consequences of not using the systematic approach include the use of more expensive and potentially more toxic agents, which can, in turn, lead to widespread resistance and difficult-to-treat superinfections. Another abuse of antimicrobial agents is administration when they are not needed such as when they are prescribed for self-limited clinical conditions that are most likely viral in origin (i.e., the common cold).

Initial selection of antimicrobial therapy is nearly always empirical, which is prior to documentation and identification of the offending organism. Infectious diseases generally are acute, and a delay in antimicrobial therapy can result in serious morbidity or even mortality. Thus empirical antimicrobial therapy selection should be based on information gathered from the patient's history and physical examination and results of Gram stains or of rapidly performed tests on specimens from the infected site. This information, combined with knowledge of the most likely offending organism(s) and an institution's local susceptibility patterns, should result in a rational selection of antibiotics to treat the patient. This chapter introduces a systematic approach to the selection of antimicrobial therapeutic regimens.

CONFIRMING THE PRESENCE OF INFECTION

FEVER

The presence of a temperature greater than the expected 37°C (98.6°F) "normal" body temperature is considered a hallmark of infectious diseases. Body temperature is controlled by the hypothalamus. In addition, the circadian rhythm, a built-in temperature cycle, is also operational. The daily temperature rhythm can vary for each individual. In a healthy person, the internal thermostat is set between the morning low temperature and the afternoon peak as controlled by the circadian rhythm. During fever, the hypothalamus is reset at a higher temperature level.

Fever is defined as a controlled elevation of body temperature above the normal range. The average normal body temperature range taken orally is 36.7 to 37°C (98.0–98.6°F). Body temperatures obtained rectally generally are 0.6°C (1°F) higher and axillary temperatures are 0.6°C (1°F) lower than oral temperatures, respectively. Skin temperatures are also less than the oral temperature but can vary depending on the specific measurement method.

Fever can be a manifestation of disease states other than infection. Collagen-vascular (autoimmune) disorders and several malignancies can have fever as a manifestation. Fever of unknown or undetermined origin is a diagnostic dilemma and is reviewed extensively elsewhere.[3]

Many drugs have been identified as causes of fever.[4] *Drug-induced fever* is defined as persistent fever in the absence of infection or other underlying condition. The fever must coincide temporally with the administration of the offending agent and disappear promptly on its withdrawal, after which the temperature remains normal. Possible mechanisms of drug-induced fever are either a hypersensitivity reaction or development of antigen-antibody complexes that result in the stimulation of macrophages and the release of interleukin 1 (IL-1). Although this is not a common drug effect (accounting for no more than 5% of all drug reactions), it should be suspected when obvious reasons for fever are not present. Almost any medication can produce fever, but β-lactam antibiotics, anticonvulsants, allopurinol, hydralazine, nitrofurantoin, sulfonamides, phenothiazines, and methyldopa appear to be responsible more often than others.

Noninfectious etiologies of fever can be referred to as "false-positives." Although these certainly can confuse the clinician, even more troublesome are false-negatives: the absence of fever in a patient with signs and symptoms consistent with an infectious disease. Careful questioning of the patient or family is vital to assess the ingestion of any medication that can mask fever (e.g., aspirin, acetaminophen, nonsteroidal antiinflammatory agents, and corticosteroids). The use of antipyretics should be discouraged during the treatment of infection unless absolutely necessary because they can mask a poor therapeutic response. Moreover, elevated body temperature, unless very high (>40.5°C [105°F]), is not harmful and may be beneficial.

SIGNS AND SYMPTOMS

White Blood Cell Count

Most infections result in elevated white blood cell (WBC) counts (leukocytosis) because of the increased production and mobilization of granulocytes (neutrophils, basophils, and eosinophils), lymphocytes, or both to ingest and destroy invading microbes. The generally accepted range of normal values for WBC counts is between 4,000 and 10,000 cells/mm^3. Values above or below this range hold important prognostic and diagnostic value.

Bacterial infections are associated with elevated granulocyte counts, often with immature forms (band neutrophils) seen in peripheral blood smears. Mature neutrophils are also referred to as *segmented neutrophils* or *polymorphonuclear* (PMN) *leukocytes*. The presence of immature forms (left shift) is an indication of an increased bone marrow response to the infection. With infection, peripheral WBC counts can be very high, but they are rarely higher than 30,000 to 40,000 cells/mm^3. Because leukocytosis indicates the normal host response to infection, low leukocyte counts after the onset of infection indicate an abnormal response and generally are associated with a poor prognosis.

The most common granulocyte defect is neutropenia, a decrease in absolute numbers of circulating neutrophils. A thorough description of the consequences of neutropenia is given in Chapter 131. Lymphocytosis, even with normal or slightly elevated total WBC counts, generally is associated with tuberculosis and viral or fungal infections. Increases in monocytes can be associated with tuberculosis or lymphoma, and increases in eosinophils can be associated with allergic reactions to drugs or infections caused by metazoa. Many types of infections can be accompanied by a completely normal WBC count and differential.

Local Signs

The classic signs of pain and inflammation can manifest as swelling, erythema, tenderness, and purulent drainage. Unfortunately, these are only visible if the infection is superficial or in a bone or joint. The manifestations of inflammation in deep-seated infections (e.g., meningitis, pneumonia, endocarditis, and urinary tract infection) must be ascertained by examining tissues or fluids. For example, the presence of neutrophils in spinal fluid, lung secretions (sputum), or urine is highly suggestive of a bacterial infection.

Symptoms referable to an organ system must be sought out carefully because not only do they help in establishing the presence of infection, but they also aid in narrowing the list of potential pathogens. For example, a febrile patient with complaints of flank pain and dysuria can well have pyelonephritis. In this situation, enteric gram-negative bacilli, especially *Escherichia coli*, are the predominant pathogens. If a febrile patient has no symptoms suggestive of an organ system but only constitutional complaints, the list of possible infectious diseases is lengthy.[3] A febrile individual with cough and sputum production probably has a pulmonary infection. What is not so evident, however, is the etiologic organism in this situation, because it can be caused by bacteria, mycobacteria, viruses, chlamydia, or mycoplasmas.[5] In this situation, attention to the patient's history and background disease states is important. Even more important is a careful examination of the infected material (in this case sputum) to ascertain the identity of the pathogen.

IDENTIFICATION OF THE PATHOGEN

MICROBIOLOGY ISSUES

1 Infected body materials must be sampled, if at all possible or practical, before institution of any antimicrobial therapy for two reasons. First, a Gram stain of the material might reveal bacteria, or an acid-fast stain might detect mycobacteria or actinomycetes. Second, a delay in obtaining infected fluids or tissues until after antimicrobial therapy is started might result in false-negative culture results or alterations in the cellular and chemical composition of infected fluids. This is particularly true in patients with urinary tract infections, meningitis, and septic arthritis.[6]

Blood cultures usually should be performed in the acutely ill febrile patient. Blood culture collection should coincide with sharp elevations in temperature, suggesting the possibility of microorganisms or microbial antigens in the bloodstream. Ideally, blood should

be obtained from peripheral sites as two sets (one set consists of an aerobic bottle and one set an anaerobic bottle) from two different sites approximately 1 hour apart. In selected infections, bacteremia is qualitatively continuous (e.g., endocarditis), so cultures can be obtained at any time.[7]

In addition to the infected materials produced by the patient (e.g., blood, sputum, urine, stool, and wound or sinus drainage), other less accessible fluids or tissues must be obtained if they are suspected to be the infected site (e.g., spinal fluid in meningitis and joint fluid in arthritis). Abscesses and cellulitic areas also should be aspirated.

INTERPRETING RESULTS

After a positive Gram stain, culture results, or both are obtained, the clinician must be cautious in determining whether the organism recovered is a true pathogen, a contaminant, or a part of the normal flora (see Chap. 113). This latter consideration is especially problematic with cultures obtained from the skin, oropharynx, nose, ears, eyes, throat, and perineum. These surfaces are heavily colonized with a wide variety of bacteria, some of which can be pathogenic in certain settings. For example, coagulase-negative staphylococci are found in cultures of all the aforementioned sites yet are seldom regarded as pathogens unless recovered from blood, venous access catheters, or prosthetic devices.

Importantly, cultures of specimens from purportedly infected sites that are obtained by sampling from or through one of these contaminated areas might contain significant numbers of the normal flora. In the case of urine cultures, the urinalysis should be used in combination with culture results to assess the presence of WBCs, nitrite, and leukocyte esterase to help confirm infection and rule out colonization.

Particularly problematic are expectorated sputum specimens that must be evaluated carefully by determination of the presence of squamous epithelial cells and leukocytes.[5] A predominance of epithelial cells in sputum specimens reduces the likelihood that recovered bacteria are pathogenic, especially when multiple types of organisms are seen on Gram stain. In contrast, the discovery of leukocytes in large numbers with one predominant type of organism is a more reliable indicator of a valid collection. In general, however, sputum evaluation has poor sensitivity and specificity as a diagnostic test.[5]

Caution also must be used in the evaluation of positive culture results from normally sterile sites (e.g., blood, cerebrospinal fluid, or joint fluid). The recovery of bacteria normally found on the skin in large quantities (e.g., coagulase-negative staphylococci or diphtheroids) from one of these sites can be a result of contamination of the specimen rather than a true infection. However, these organisms can be pathogenic in certain settings.

Gram-staining techniques, culture methods, and serologic identification, as well as susceptibility testing, are discussed in detail in Chapter 113. Emphasis must be placed on the proper collection and handling of specimens and careful assessment of Gram stain or other test results in guiding the clinician toward appropriate selection of initial antimicrobial therapy.[8]

SELECTION OF PRESUMPTIVE THERAPY

2 To select rational antimicrobial therapy for a given clinical situation, a variety of factors must be considered. These include the severity and acuity of the disease, host factors, factors related to the drugs used, and the necessity for using multiple agents. In addition, there are generally accepted drugs of choice for the treatment of most pathogens (see Appendix 114–1).

Drugs of choice are compiled from a variety of sources and are intended as guidelines rather than as specific rules for antimicrobial use. These choices are influenced by local antimicrobial susceptibility data rather than information published by other institutions or national compilations. Each institution should publish an annual summary of antibiotic susceptibilities (antibiogram) for organisms cultured from patients. Antibiograms contain both the number of nonduplicate isolates for common species and the percentage susceptible to the antibiotics tested. To further guide empirical antibiotic therapy, some hospitals publish unit-specific antibiograms in unique patient care areas, such as intensive care units or burn units.

Susceptibility of bacteria can differ substantially among hospitals within a community. For example, the prevalence of hospital-acquired methicillin-resistant *Staphylococcus aureus* (HA-MRSA) in some centers is quite high, whereas in other centers the problem might be nonexistent. This particular situation will influence the selection of therapy for possible *S aureus* infection, where the clinician must choose either a β-lactam or vancomycin. The problem of differing susceptibilities is not limited only to gram-positive bacteria but also is evident gram-negative organisms, and all drug classes are affected.

Empirical therapy is directed at organisms that are known to cause the infection in question. These organisms are discussed for different sites of infection in Chapters 115 to 132. To define the most likely infecting organisms, a careful history and physical examination must be performed. The place where the infection was acquired should be determined, for example, the home (community acquired), nursing home environment, or hospital acquired (nosocomial). Nursing home patients can be exposed to potentially more resistant organisms because they are often surrounded by ill patients who are receiving antibiotics. Other important questions to ask infected patients regarding the history of present illness include the following:

1. Are any other people sick at home, especially children?
2. Are any unusual pets kept in the home such as pigeons?
3. Where are you employed (i.e., are you exposed to contaminated meat or infectious biohazards)?
4. Has there been any recent travel (i.e., to endemic areas of fungal infections or developing countries)?

HOST FACTORS

Several host factors should be considered when evaluating a patient for antimicrobial therapy. The most important factors are drug allergies, age, pregnancy, genetic or metabolic abnormalities, renal and hepatic function, site of infection, concomitant drug therapy, and underlying disease states.

Allergy

3 Allergy to an antimicrobial agent generally precludes its use. Careful assessment of allergy histories must be performed because many patients confuse common adverse drug effects (i.e., gastrointestinal disturbance) with true allergic reactions.[9] Among the most commonly cited antimicrobial allergies are those to penicillin, penicillin-related compounds, or both. In the absence of complete penicillin skin testing capabilities, a rule of thumb for giving cephalosporins to patients allergic to penicillin is to avoid giving them to patients who give a good history for immediate or accelerated reactions (e.g., anaphylaxis, laryngospasm) and to give them under close supervision in patients with a history of delayed reactions, such as a rash.[10] If a gram-negative infection is suspected or documented, therapy with a monobactam may be appropriate because cross-reactivity with other β-lactams is nonexistent.

Age

The patient's age is an important factor both in trying to identify the likely etiologic agent and in assessing the patient's ability to eliminate the drug(s) to be used. The best example of an age determinant of organisms is in bacterial meningitis, where the pathogens differ as the patient grows from the neonatal period through infancy and childhood into adulthood.[6]

In the case of the neonate, hepatic and liver functions are not well developed. Therefore, bilirubin excretion is decreased resulting in increased concentration of unconjugated bilirubin that can cause kernicterus. Neonates (especially when premature) can develop kernicterus when given sulfonamides. This results from displacement of bilirubin from serum albumin. In addition, neonates have more body water content that results in a larger volume of distribution leading to adjustments in antibiotic dosing regimens. Additional special drug considerations for pediatric patients include low frequency of adverse effects and compliance-enhancing features (e.g., absorption not affected by food, once- to twice-daily dosing, and good taste).[11]

The major physiologic change in persons older than 65 years of age is a decline in the number of functioning nephrons that, in turn, results in decreased renal function.[12] This is usually manifested by an increased incidence of side effects caused by antimicrobials that are eliminated renally. For example, renal toxicity caused by aminoglycosides may be apparent much sooner during therapy than in younger patients.

Pregnancy

During pregnancy, not only is the fetus at risk for drug teratogenicity, but also the pharmacokinetic disposition of certain drugs can be altered.[13] Penicillins, cephalosporins, and aminoglycosides are cleared from the peripheral circulation more rapidly during pregnancy. This is probably a result of marked increases in intravascular volume, glomerular filtration rate, and hepatic and metabolic activities. The net result is that maternal serum antimicrobial concentrations can be as much as 50% lower during this period than in the nonpregnant state. Increased dosages of certain compounds might be necessary to achieve therapeutic levels during late pregnancy.

Metabolic Abnormalities

Inherited or acquired metabolic abnormalities will influence the therapy of infectious diseases in a variety of ways. For example, patients with impaired peripheral vascular flow may not absorb drugs given by intramuscular injection. In addition, certain metabolic states can predispose patients to enhanced drug toxicity. For instance, patients who are phenotypically slow acetylators of isoniazid are at greater risk for peripheral neuropathy.[14] Patients with severe deficiency of glucose-6-phosphate dehydrogenase can develop significant hemolysis when exposed to such drugs as sulfonamides, nitrofurantoin, nalidixic acid, antimalarials, and dapsone. Although mild deficiencies are found in African Americans, the more severe forms of the disease generally are confined to persons of eastern Mediterranean origin.

Organ Dysfunction

4 Patients with diminished renal or hepatic function or both will accumulate certain drugs unless the dosage is adjusted.[15,16] Recommendations for dosing antibiotics in patients with liver dysfunction are not as formalized as guidelines for patients with renal dysfunction. Antibiotics that should be adjusted in severe liver disease include clindamycin, erythromycin, metronidazole, and rifampin. Significant accumulation can occur when both liver dysfunction and renal dysfunction are present for the following drugs: cefotaxime, nafcillin, piperacillin, and sulfamethoxazole.

Concomitant Drugs

5 Any concomitant therapy that the patient is receiving can influence the drug selection, dose, and monitoring. For instance, administration of isoniazid to a patient who is also receiving phenytoin can result in phenytoin toxicity secondary to inhibition of phenytoin metabolism by isoniazid. Furthermore, drugs that possess similar adverse-effect profiles can increase the risk for effects, (i.e., two drugs that cause nephrotoxicity or neutropenia). A detailed review of drug interactions is beyond the scope of this chapter, but an excellent textbook on this subject is available.[17] Lists of potentially severe drug-drug interactions are provided in Table 114–2.

Concomitant Disease States

Concomitant disease states can influence the selection of therapy. Certain diseases will predispose patients to a particular infectious disease or will alter the type of infecting organism. For example, patients with diabetes mellitus and the resulting peripheral vascular disease often develop infections of the lower extremity soft tissue. Moreover, the alterations in peripheral blood flow associated with the disease and perhaps altered immunity make such infections more difficult to treat than in nondiabetics. Patients with chronic lung disease or cystic fibrosis develop frequent pulmonary infections that can be caused by somewhat different microorganisms than are found in otherwise normal hosts.

Patients with immunosuppressive diseases, such as malignancies or acquired immunologic deficiencies, are highly predisposed to infections, and the types of causative or pathogenic organisms can be vastly different from what would be expected (see Chap. 131). For instance, patients undergoing chemotherapy for acute forms of leukemia often are profoundly granulocytopenic and are predisposed to infections caused by bacteria and fungi.[18] Patients with the acquired immunodeficiency syndrome (AIDS) often become infected with an enormous variety of organisms (see Chap. 134).

Many factors predisposing to infection are related to disruption of the host's integumentary barriers. For example, trauma, burns, and iatrogenic wounds induced in surgery can lead to a substantial risk of infection depending on the severity and location of the injury or disruption. For a complete discussion of the various risks involved in surgical procedures, see Chapter 132.

DRUG FACTORS

Pharmacokinetic and Pharmacodynamic Considerations

Integration of both pharmacokinetic and pharmacodynamic properties of an agent is important when choosing antimicrobial therapy to ensure efficacy and to prevent resistance.[19] Early researchers relied solely on pharmacokinetic properties such as the area under the (drug concentration) curve (AUC), maximum observed concentration (peak), and drug half-life to optimize therapy. Pharmacodynamics is the study of the relationship between drug concentration and the effects on the microorganism. There is an important relationship between both pharmacokinetic and microbiologic parameters that has resulted in measurements such as AUC:minimal inhibitory concentration (MIC) ratio, peak: MIC ratio, and time (T) the concentration is above MIC ($T > MIC$).[19–23]

Aminoglycosides exhibit concentration-dependent bactericidal effects. An example of the integration of pharmacokinetics and microbiological activity is the use of high-dose, once-daily aminoglycosides. For these regimens, the drug is given as a single large daily dose to maximize the peak:MIC ratio. Aminoglycosides also

TABLE 114-2 Major Drug Interactions with Antimicrobials

Antimicrobial	Other Agent(s)	Mechanism of Action/Effect	Clinical Management
Aminoglycosides	Neuromuscular blocking agents	Additive adverse effects	Avoid
	Nephrotoxins (N) or ototoxins (O) (e.g., amphotericin B (N) cisplatin (N/O), cyclosporine (N), furosemide (O), NSAIDs (N), radio contrast (N), vancomycin (N)	Additive adverse effects	Monitor aminoglycoside SDC and renal function
Amphotericin B	Nephrotoxins (e.g., aminoglycosides, cidofovir, cyclosporine, foscarnet, pentamidine)	Additive adverse effects	Monitor renal function
Azoles	See Chap. 130		
Chloramphenicol	Phenytoin, tolbutamide, ethanol	Decreased metabolism of other agents	Monitor phenytoin SDC, blood glucose
Foscarnet	Pentamidine IV	Increased risk of severe nephrotoxicity/ hypocalcemia	Monitor renal function/serum calcium
Isoniazid	Carbamazepine, phenytoin	Decreased metabolism of other agents (nausea, vomiting, nystagmus, ataxia)	Monitor drug SDC
Macrolides/azalides	Digoxin	Decreased digoxin bioavailability and metabolism	Monitor digoxin SDC; avoid if possible
	Theophylline	Decreased metabolism of theophylline	Monitor theophylline SDC
Metronidazole	Ethanol (drugs containing ethanol)	Disulfiram-like reaction	Avoid
Penicillins and cephalosporins	Probenecid, aspirin	Blocked excretion of β-lactams	Use if prolonged high concentration of β-lactam desirable
Ciprofloxacin/norfloxacin	Theophylline	Decreased metabolism of theophylline	Monitor theophylline
Quinolones	Classes Ia and III Antiarrhythmics	Increased Q-T interval	Avoid
	Multivalent cations (antacids, iron, sucralfate, zinc, vitamins, dairy, citric acid) didanosine	Decreased absorption of quinolone	Separate by 2 hours
Rifampin	Azoles, cyclosporine, methadone propranolol, PIs, oral contraceptives, tacrolimus, warfarin	Increased metabolism of other agent	Avoid if possible
Sulfonamides	Sulfonylureas, phenytoin, warfarin	Decreased metabolism of other agent	Monitor blood glucose, SDC, PT
Tetracyclines	Antacids, iron, calcium, sucralfate	Decreased absorption of tetracycline	Separate by 2 hours
	Digoxin	Decreased digoxin bioavailability and metabolism	Monitor digoxin SDC; avoid if possible

PI, protease inhibitor; PT, prothrombin time; SDC, serum drug concentrations.
Azalides: azithromycin; azoles: fluconazole, itraconazole, ketoconazole, and voriconazole; macrolides: erythromycin, clarithromycin; protease inhibitors: amprenavir, indinavir, lopinavir/ritonavir, nelfinavir, ritonavir, and saquinavir; quinolones: ciprofloxacin, gemifloxacin, levofloxacin, moxifloxacin.

possess a postantibiotic effect (persistent suppression of organism growth after concentrations decrease below the MIC) that appears to contribute to the success of high-dose, once-daily administration. Fluoroquinolones exhibit concentration-dependent killing activity, but optimal killing appears to be characterized by the AUC:MIC ratio.

β-Lactams display time-dependent bactericidal effects. Killing activity is enhanced only marginally if drug concentration exceeds the MIC. Therefore, the important pharmacodynamic relationship for these antimicrobials is the duration that drug concentrations exceed the MIC (T > MIC). Effective dosing regimens require serum drug concentrations to exceed the MIC for at least 40% to 50% of the dosing interval. Frequent small doses, continuous infusion, or prolonged infusion of β-lactams appears to be correlated with positive outcomes.

A detailed discussion on antimicrobial pharmacokinetics-pharmacodynamics is beyond the scope of this chapter. However, excellent sources of information on this topic are available.[19–23]

Tissue Penetration

The importance of tissue penetration varies with site of infection. Some of the difficulties in interpreting data include a lack of correlation with clinical outcomes and poor understanding of whether the antimicrobial agents are present in a biologically active form. An example of the former problem is the recognized efficacy of drugs with low biliary fluid concentrations in the treatment of cholecystitis, cholangitis, or both and the absence of the enhanced efficacy of drugs whose primary route of elimination is biliary excretion of active drug. An example of the latter difficulty is with penetration to deep infections, such as abscesses, where various factors such as acid pH, WBC products, and various enzymes can inactivate even high concentrations of certain drugs.

The central nervous system (CNS) is one body site where antimicrobial penetration is relatively well defined, and correlations with clinical outcomes are established.[6,24] Cerebrospinal fluid (CSF) concentrations of antimicrobial agents necessary to cure bacterial meningitis have been defined, and drugs that do not reach significant concentrations in the CSF should either be avoided or instilled directly, if feasible.

Caution must be exercised when selecting an antimicrobial agent for clinical use on the basis of tissue or fluid penetration. Body fluids where drug concentration data are clinically relevant include CSF, urine, synovial fluid, and peritoneal fluid. Apart from these areas, more attention should be paid to clinical efficacy, antimicrobial spectrum, toxicity, and cost than to comparative data on penetration into a given body site.

The proper route of administration for an antimicrobial depends on the site of infection. Parenteral therapy is warranted when patients are being treated for febrile neutropenia or deep-seated infections such as meningitis, endocarditis, and osteomyelitis. Severe pneumonia often is treated initially with intravenous antibiotics and switched to oral therapy as clinical improvement is evident.[5,25] Patients treated in the ambulatory setting for upper respiratory tract infections (e.g., pharyngitis, bronchitis, sinusitis, and otitis media), lower respiratory tract infections, skin and soft tissue infections, uncomplicated urinary tract infections, and selected sexually transmitted diseases can usually receive oral therapy.

Drug Toxicity

It is incumbent on health professionals to avoid toxic drugs whenever possible. Antibiotics associated with CNS toxicities, usually when not dose-adjusted for renal function, include penicillins, cephalosporins, quinolones, and imipenem. Hematologic toxicities generally are manifested with prolonged use of nafcillin (neutropenia), piperacillin (platelet dysfunction), cefotetan (hypoprothrombinemia), chloramphenicol (bone marrow suppression, both idiosyncratic and dose-related toxicity), and trimethoprim (megaloblastic anemia). Reversible nephrotoxicity classically is associated with aminoglycosides and vancomycin. Reversible ototoxicity can occur with aminoglycosides or erythromycin. In the outpatient setting, patients must be counseled regarding photosensitivity with azithromycin, quinolones, tetracyclines, pyrazinamide, sulfamethoxazole, and trimethoprim. Lastly, all antibiotics have been implicated in causing diarrhea and colitis secondary to *Clostridium difficile*[26] (see Chap. 122).

Aside from consideration of drug toxicity, some antimicrobial use requires more intensive risk-benefit analysis. An example of this is the decision to use isoniazid prophylactically to prevent tuberculosis. Because the hepatotoxicity of isoniazid increases in frequency with age, older persons (>45 years of age) who are candidates for isoniazid prophylaxis (positive skin test) must have additional risk factors for tuberculosis to balance the potential toxic effects. These include evidence of recent skin-test conversion, immunosuppression, or previous gastrectomy. Older patients without additional risk factors are more likely to suffer toxicity from isoniazid than derive benefit from its use.[27]

Cost

The costs of drug therapy are increasing dramatically, especially as new products, derived from biotechnology, are introduced. Greater attention is being paid to the pharmacoeconomics of drug therapy, where patient outcomes are valued, and the costs to arrive at those outcomes are estimated. Understanding the true cost of antimicrobial therapy is more important than ever. The total cost of antimicrobial therapy includes much more than just the acquisition cost of the drugs.[28]

Many ancillary costs and factors affect the true cost of therapy. These include factors such as storage, preparation, distribution, and administration, as well as all the costs incurred from monitoring for adverse effects and factors such as length of hospitalization, readmissions, and all directly provided healthcare goods and services. More difficult to value but equally as important are indirect costs such as patient quality-of-life issues. Pharmacoeconomic and outcomes analyses are becoming more widely applied and used in order to derive values such as cost-benefit ratios and the cost-effectiveness of various products as compared with other products. A great deal more research in this area is needed, and multidisciplinary, collaborative efforts with the involvement of pharmacy, medicine, nursing, and microbiology are essential.

Many oral antimicrobials have been approved, including cephalosporins, linezolid, and fluoroquinolones, which can be used in place of more expensive parenteral therapy. These agents offer extended-spectrum killing activity, increased tissue penetration, and excellent safety and pharmacokinetic profiles. When oral therapy is being considered, the choice between convenient once-a-day expensive agents versus multiple-dose inexpensive agents arises. It is easy to calculate the difference in acquisition cost; however, the overall cost between agents is more difficult to determine. Factors to weigh include safety, effectiveness, tolerability, patient compliance, and potential drug–drug interactions. In some instances, more expensive agents can be warranted to avoid adverse outcomes.

COMBINATION ANTIMICROBIAL THERAPY

6 In selecting a drug regimen for a given patient, consideration must be given to the necessity of using more than one drug. Combinations of antimicrobials generally are used to broaden the spectrum of coverage for empirical therapy, achieve synergistic activity against the infecting organism, and prevent the emergence of resistance.

Broadening the Spectrum of Coverage

Increasing the coverage of antimicrobial therapy generally is necessary in mixed infections where multiple organisms are likely to be present. This is the case in intraabdominal and female pelvic infections, in which a variety of aerobic and anaerobic bacteria can produce disease.[29] Traditionally, a combination of a drug active against aerobic gram-negative bacilli, such as an aminoglycoside, and a drug active against anaerobic bacteria, such as metronidazole or clindamycin, is selected. Newer compounds, which possess good activity against both of these types of organisms, such as the β-lactam/β-lactamase inhibitor combinations, carbapenems or glycylcyclines, might be adequate to replace the combination and thereby reduce the cost of therapy. The other clinical situation in which an increased spectrum of activity is desirable is with nosocomial infections.[25]

Synergism

The achievement of synergistic antimicrobial activity is advantageous for infections caused by enteric gram-negative bacilli in immunosuppressed patients. Laboratory tests to identify synergy between antibiotic combinations are described in Chapter 113. Traditionally, combinations of aminoglycosides and β-lactams have been used because these drugs together generally act synergistically against a wide variety of bacteria. However, the data supporting superior efficacy of synergistic over nonsynergistic combinations are weak. At best, it would appear that synergistic combinations produce better results in certain infections caused by *P aeruginosa* and *Enterococcus* species.[30–32]

The most obvious example of the use of synergy is the treatment of enterococcal endocarditis. The causative organism is usually only inhibited by penicillins, but it is killed rapidly by the addition of streptomycin or gentamicin to a penicillin.[7] The need for bactericidal activity in the treatment of endocarditis underscores the need for these synergistic combinations.

Preventing Resistance

The use of combinations to prevent the emergence of resistance is applied widely but not often realized. The only circumstance where this has been clearly effective is in the treatment of tuberculosis. The prevalence of resistance to a first-line drug such as isoniazid or rifampin in a population of organisms may be as high as 1 in 10^6 to 10^8. Because the bacterial load in a patient with active tuberculosis often exceeds this, two drugs are given to reduce the likelihood of encountering resistance to less than 1 in 10.[27] There is ample evidence from in vitro data and experimental bacterial infections that combinations of drugs with different mechanisms are effective in the prevention of the emergence of resistance. Data from clinical trials, however, are either conflicting or do not convincingly support this concept.[32]

Disadvantages of Combination Therapy

Although there are potentially beneficial effects from combining drugs, there also are potential disadvantages, including increased cost, greater risk of drug toxicity such as nephrotoxicity with aminoglycosides, amphotericin, and possibly vancomycin, and superinfection with even more resistant bacteria.[30–32]

The combination of two or more antibiotics can result in antagonistic effects. Clinically, the effect of antagonism may be evident when one drug induces β-lactamase production and another drug is β-lactamase unstable. Cefoxitin and imipenem are examples of drugs capable of inducing β-lactamases and may result in more rapid inactivation of penicillins when used together.

MONITORING THERAPEUTIC RESPONSE

7 After antimicrobial therapy has been instituted, the patient must be monitored carefully for a therapeutic response. Culture and sensitivity reports from specimens sent to the microbiology laboratory must be reviewed and the therapy changed accordingly. Use of agents with the narrowest spectrum of activity against identified pathogens is recommended. If anaerobes are suspected, even if they are not identified, anaerobic therapy should be continued.

Patient monitoring should include many of the same parameters used to diagnose the infection. The WBC count and temperature should start to normalize. Physical complaints from the patient also should diminish (i.e., decreased pain, shortness of breath, cough, or sputum production). Appetite should improve. However, radiologic improvement can lag behind clinical improvement.

Determinations of serum (or other fluid) levels of antimicrobials can be useful in ensuring outcome, preventing toxicity, or both. There are only a few antimicrobials that require serum concentration monitoring and then only in selected situations. These include the aminoglycosides, flucytosine, and chloramphenicol. Achievement of adequate aminoglycoside concentrations within the first few days of therapy of gram-negative infection has been correlated with better therapeutic outcome.[33]

Changes in the volume of distribution can have a significant impact on the efficacy, safety, or both of therapy. An unexpectedly low volume of distribution (such as in the dehydrated patient) will result in higher, potentially toxic drug concentrations, whereas a larger-than-expected volume of distribution (such as in patients with edema or ascites) will result in low, potentially subtherapeutic concentrations. The most effective methods use measured serum concentrations of the drugs rather than estimations from renal function tests to assess true drug clearance from the body.

8 As patients improve clinically, the route of administration should be reevaluated. Streamlining therapy from parenteral to oral (switch therapy) has become an accepted practice for many infections.[5] Criteria that should be present to justify a switch to oral therapy include (1) overall clinical improvement, (2) lack of fever for 8 to 24 hours, (3) decreased WBC count, and (4) a functioning gastrointestinal tract. Drugs that exhibit excellent oral bioavailability when compared with intravenous formulations include ciprofloxacin, clindamycin, doxycycline, levofloxacin, metronidazole, moxifloxacin, linezolid, and trimethoprim-sulfamethoxazole.

FAILURE OF ANTIMICROBIAL THERAPY

9 A variety of factors may be responsible for an apparent lack of response to therapy. Patients who fail to respond over 2 to 3 days require a thorough reevaluation. It is possible that the disease is not infectious or is nonbacterial in origin, or there is an undetected pathogen in a polymicrobial infection. Other factors include those directly related to drug selection, the host, or the pathogen. Laboratory error in identification, susceptibility testing, or both (presence of inoculum effect or resistant subpopulations) is a rare cause of antimicrobial failure.

Failures Caused by Drug Selection

Factors related directly to the drug selection include an inappropriate drug selection, dosage, or route of administration. Malabsorption of a drug product because of gastrointestinal disease, such as a short-bowel syndrome, or a drug interaction, such as complexation of fluoroquinolones with multivalent cations resulting in reduced absorption, can lead to potentially subtherapeutic serum concentrations. Accelerated drug elimination is also possible. This can occur in patients with cystic fibrosis or during pregnancy, when more rapid clearance or larger volumes of distribution can result in low serum concentrations, particularly for aminoglycosides. A common cause of failure of therapy is poor penetration into the site of infection. This is especially true for sites such as the CNS, eye, and prostate gland. Drug failure also can result from drugs that are highly protein bound or that are chemically inactivated at the site of infection.

Failures Caused by Host Factors

Host defenses must be considered when evaluating a patient who is not responding to antimicrobial therapy. Patients who are immunosuppressed (e.g., granulocytopenia from chemotherapy or AIDS) may respond poorly to therapy because their defenses are inadequate to eradicate the infection despite seemingly adequate drug regimens. A good example is the poor response of infection in granulocytopenic patients that is seen when their WBC counts remain low during therapy. This contrasts with a much better response when granulocyte counts increase during therapy.

Other host factors are related to the need for surgical drainage of abscesses or removal of foreign bodies, necrotic tissue, or both. If these situations are not corrected, they result in persistent infection and, occasionally, bacteremia despite adequate antimicrobial therapy.

Failures Caused by Microorganisms

There are two types of resistance, intrinsic and acquired resistance. Intrinsic resistance is when the antimicrobial agent never had activity against the bacterial species. For example, gram-negative bacteria are naturally resistant to vancomycin because the drug cannot penetrate the outer membrane of gram-negative bacteria. Acquired resistance is when the antimicrobial agent was originally active against the bacterial species but the genetic makeup of the bacteria has changed so the drug can no longer be effective.[34]

The strategies used by bacteria to develop acquired resistance are primarily classified into four general mechanisms of resistance: (1) alteration in the target site, (2) change in membrane permeability, (3) efflux pump, and (4) drug inactivation. Bacteria can use one or more of these mechanisms against a specific antibiotic class. Furthermore, a single mechanism of resistance can result in resistance to multiple related or unrelated classes of antibiotics.

Drug inactivation either through β-lactamases or aminoglycoside modifying enzymes is the predominant mechanism of resistance. For example, β-lactamases can either be plasmid or chromosomally mediated. In addition, the expression of β-lactamases can be induced or constitutive. There are now multiple types and classes of β-lactamases identified which is beyond the scope of this chapter. However, there are several outstanding papers discussing all of the different types of β-lactamases.[35–37]

The increase in resistance among bacteria is believed to be a result of continued overuse of antimicrobials in the community, as well as in hospitals, and the increasing prevalence of immunosuppressed patients receiving long-term suppressive antimicrobials for the prevention of infections. These resistance patterns are regionally variable, and susceptibility patterns in the community (or hospital) should be monitored closely to promote rational antimicrobial selection.[34]

Enterococci have been isolated with multiple resistance patterns. They may be resistant to β-lactams (by virtue of β-lactamase production, altered penicillin-binding proteins [PBPs], or both),

vancomycin (via alterations in peptidoglycan synthesis), and high levels of aminoglycosides (via enzymatic degradation). Pneumococci resistant to penicillins, certain cephalosporins, and macrolides are increasingly common. These organisms generally are susceptible to vancomycin, the new fluoroquinolones, and cefotaxime or ceftriaxone. However, antimicrobial agents such as linezolid, daptomycin, telavancin, and tigecycline have been targeted at resistant gram-positive bacteria.

Treatment of an infection caused by *Enterobacter*, *Citrobacter*, *Serratia,* or *P aeruginosa* with a third-generation cephalosporin or aztreonam may produce an initial clinical response by eradicating all the susceptible bacteria in the population. Within a few days, however, the highly resistant subpopulations have a selective advantage and can overgrow the infection site to produce a relapse.[37] These bacteria usually retain susceptibility to aminoglycosides, carbapenems, and fluoroquinolones but are resistant to all other β-lactams. Host defenses are extremely important in this scenario. Debilitated patients with pulmonary infections, abscesses, or osteomyelitis are at high risk for drug failure. In these situations, a combination regimen to prevent the emergence of resistance or the use of carbapenem or a fluoroquinolone may be warranted for empirical therapy.

ANTIMICROBIAL USE MANAGEMENT

ANTIBIOTIC FORMULARY

Institutions must decide which antibiotics to include on their formularies. The actual decision to have a formulary remains controversial; however, restricting choices does encourage familiarity with a core of antibiotics for residents and attending physicians. Open formularies allow the empirical use of any commercially available antibiotics, with recommended guidelines for changes when culture and sensitivity results are finalized. Many institutions have developed an antibiotic stewardship team.[38,39] The team is generally a multidisciplinary group including representation from microbiology, infection control, administration, information technology, pharmacy including an infectious disease trained clinical pharmacists, and physicians from several disciplines, including infectious disease. The actual implementation of the guidelines and restrictions recommended by such groups requires the cooperation of the entire medical staff. Education is vital to the success of the antibiotic formulary.[38,39]

ANTIMICROBIAL CYCLING

An interesting topic in formulary management that gained interest and scientific research is *antimicrobial cycling.* Antimicrobial cycling is a predetermined change in an antimicrobial recommendation for empirical therapy of a specific infection at a predetermined time. It also has been called *rotation of antimicrobials.* This strategy should not be confused with *antimicrobial switch therapy,* which involves changes in the route of administration of antimicrobial therapy (i.e., intravenous to oral).

Antimicrobial cycling is employed as a mechanism to reduce or prevent antimicrobial resistance. *Proactive cycling* is a planned switch to preempt resistance at a predetermined point or series of points with a predetermined schedule. *Reactive cycling* is a response to high or unacceptable resistance and is often a one-time switch. Most programs incorporate aspects of both types of cycling. Cycling implies returning to the original drug after other choices have been used. Rotation implies several planned changes.

Antimicrobial cycling is based on the assumptions that the resistance problem is (1) caused by the overuse of a particular agent or class of agents and (2) that discontinuation of the particular agent or class of agents will restore susceptibility. These assumptions correlate best with nosocomial gram-negative organisms that can rapidly develop resistance. Theoretically, antimicrobial agents should be sequenced in such an order that mechanisms of resistance do not overlap (i.e., changing drug classes).[39,40] However, data have provided insufficient evidence to clearly demonstrate the usefulness of antibiotic cycling.

KEEPING CURRENT

Attention must be paid to the literature on antimicrobials to assist in the selection of therapy. The results from prospective, controlled, randomized clinical trials should be evaluated whenever possible when considering appropriate antimicrobial therapy. Results from prelicensing open trials offer only limited information that can be useful in this regard because patients in these trials generally are not seriously ill and are not infected with multiple resistant bacteria. Other confounding factors found in most clinical situations are excluded by virtue of the study design. Therefore, comparative data in more seriously ill patients are essential for the appropriate application of new agents.

Postmarketing trials are also important because results can demonstrate superiority of one regimen over another, either in efficacy, safety, or cost-effectiveness. Appropriate antimicrobial therapy can change as new organisms are discovered, susceptibility patterns change, new drugs become available, and new clinical trial results are published. Classical thinking in the treatment of infectious diseases will continue to change and evolve to maintain antimicrobial efficacy. Optimal use of modern antimicrobials is just beginning to be defined.

ABBREVIATIONS

AUC: area under the curve

IL: interleukin

MIC: minimal inhibitory concentration

PBP: penicillin-binding protein

PMN: polymorphonuclear leukocytes

WBC: white blood cell

Appendix 114-1
Drugs of Choice, First Choice, *Alternative(s)*

GRAM-POSITIVE COCCI

Enterococcus faecalis (generally not as resistant to antibiotics as *Enterococcus faecium*)

- Serious infection (endocarditis, meningitis, pyelonephritis with bacteremia)
  - Ampicillin (or penicillin G) + (gentamicin or streptomycin)
  - *Vancomycin* + (*gentamicin or streptomycin*), *daptomycin*, *linezolid*, *telavancin*, *tigecycline*[a]
- Urinary tract infection (UTI)
  - Ampicillin, amoxicillin
  - *Fosfomycin* or *nitrofurantoin*

E faecium (generally more resistant to antibiotics than *E faecalis*)

- Recommend consultation with infectious disease specialist
  - Linezolid, quinupristin/dalfopristin, daptomycin, tigecycline[a]

Staphylococcus aureus/Staphylococcus epidermidis

- Methicillin (oxacillin)-sensitive
  - Nafcillin or oxacillin
  - *FGC*,[b,c] *trimethoprim-sulfamethoxazole*, *clindamycin*, *BL/BLI*[j]
- Hospital-acquired methicillin (oxacillin)–resistant
  - Vancomycin ± (gentamicin or rifampin)
  - *Daptomycin*, *linezolid*, *telavancin*, *tigecycline*,[a] *trimethoprim-sulfamethoxazole*, or *quinupristin-dalfopristin*
- Community-acquired methicillin (oxacillin)-resistant
  - Clindamycin, trimethoprim-sulfamethoxazole, doxycycline[a]
  - *Daptomycin*, *linezolid*, *telavancin*, *tigecycline*,[a] or *vancomycin*

Streptococcus (groups A, B, C, G, and *Streptococcus bovis*)

- Penicillin G or V or ampicillin
- *FGC*,[b,c] *erythromycin*, *azithromycin*, *clarithromycin*

Streptococcus pneumoniae

- Penicillin-sensitive (MIC <0.1 mcg/mL)
  - Penicillin G or V or ampicillin
  - *FGC*,[b,c] *doxycycline*,[a] *azithromycin*, *clarithromycin*, *erythromycin*
- Penicillin intermediate (MIC 0.1–1.0 mcg/mL)
  - High-dose penicillin (12 million units/day for adults) or ceftriaxone[c] or cefotaxime[c]
  - *Levofloxacin*,[a] *moxifloxacin*,[a] *gemifloxacin*,[a] *or vancomycin*
- Penicillin-resistant (MIC ≥1.0 mcg/mL)
  - Recommend consultation with infectious disease specialist.
    - *Vancomycin ± rifampin*
    - *Per sensitivities: cefotaxime*,[c] *ceftriaxone*,[c] *levofloxacin*,[a] *moxifloxacin*,[a] *or gemifloxacin*[a]

Streptococcus, viridans group

- Penicillin G ± gentamicin[d]
- *Cefotaxime*,[c] *ceftriaxone*,[c] *erythromycin*, *azithromycin*, *clarithromycin*, or *vancomycin ± gentamicin*

GRAM-NEGATIVE COCCI

Moraxella (Branhamella) catarrhalis

- Amoxicillin-clavulanate, ampicillin-sulbactam
- *Trimethoprim-sulfamethoxazole*, *erythromycin*, *azithromycin*, *clarithromycin*, *doxycycline*,[a] *SGC*,[c,e] *cefotaxime*,[c] *ceftriaxone*,[c] or *TGC PO*[c,f]

Neisseria gonorrhoeae (also give concomitant treatment for *Chlamydia trachomatis*)

- Disseminated gonococcal infection
  - Ceftriaxone[c] or cefotaxime[c]
  - *Oral follow-up*: *cefpodoxime*,[c] *ciprofloxacin*,[a] or *levofloxacin*[a]
- Uncomplicated infection
  - Ceftriaxone,[c] cefotaxime,[c] or cefpodoxime[c]
  - *Ciprofloxacin*[a] or *levofloxacin*[a]

Neisseria meningitides

- Penicillin G
- *Cefotaxime*[c] or *ceftriaxone*[c]

GRAM-POSITIVE BACILLI

Clostridium perfringens

- Penicillin G ± clindamycin
- *Metronidazole*,[a] *clindamycin*, *doxycycline*,[a] *cefazolin*,[c] *carbapenem*[g,h]

Clostridium difficile

- Oral metronidazole[a]
- *Oral vancomycin*

GRAM-NEGATIVE BACILLI

Acinetobacter spp

- Doripenem, imipenem or meropenem ± aminoglycoside[i] (amikacin usually most effective)
- *Ampicillin-sulbactam*, *colistin*,[h] or *tigecycline*[a]

Bacteroides fragilis (and others)

- Metronidazole[a]
- *BL/BLI*,[j] *clindamycin*, *cefoxitin*,[c] *cefotetan*,[c] or *carbapenem*[g,h]

Enterobacter spp

- Carbapenem,[g] or cefepime ± aminoglycoside[i]
- *Ciprofloxacin*,[a] *levofloxacin*,[a] *piperacillin-tazobactam*, *ticarcillin-clavulanate*

Escherichia coli

- Meningitis
  - Cefotaxime,[c] ceftriaxone,[c] meropenem
- Systemic infection
  - Cefotaxime[c] or ceftriaxone[c]
  - *BL/BLI*,[j] *fluoroquinolone*,[a,k] *carbapenem*[g,h]
- Urinary tract infection
  - Most oral agents: check sensitivities
  - Ampicillin, amoxicillin-clavulanate, doxycyline,[a] or cephalexin[c]
  - *Aminoglycoside*,[i] *FGC*[b,c] *nitrofurantoin*, *fluoroquinolone*[a,k]

Gardnerella vaginalis

- Metronidazole[a]
- *Clindamycin*

Haemophilus influenzae

- Meningitis
  - Cefotaxime[c] or ceftriaxone[c]
  - *Meropenem*[h]

- Other infections
  - BL/BLI,[j] or if β-lactamase-negative, ampicillin or amoxicillin
  - *Trimethoprim-sulfamethoxazole, cefuroxime,[c] azithromycin, clarithromycin*, or *fluoroquinolone*[a,k]

Klebsiella pneumoniae

- BL/BLI,[j] cefotaxime,[c] ceftriaxone,[c] cefepime[c]
- *Carbapenem,[g,h] fluoroquinolone*[a,k]

Legionella spp

- Azithromycin, erythromycin ± rifampin, or fluoroquinolone[a,k]
- *Trimethoprim-sulfamethoxazole, clarithromycin, or doxycycline*[a]

Pasteurella multocida

- Penicillin G, ampicillin, amoxicillin
- *Doxycycline,[a] BL/BLI,[j] trimethoprim-sulfamethoxazole or ceftriaxone*[c]

Proteus mirabilis

- Ampicillin
- *Trimethoprim-sulfamethoxazole*

Proteus (indole-positive) (including *Providencia rettgeri*, *Morganella morganii*, and *Proteus vulgaris*)

- Cefotaxime,[c] ceftriaxone,[c] or fluoroquinolone[a,k]
- *BL/BLI,[j] aztreonam,[l] aminoglycosides,[i] carbapenem*[g,h]

Providencia stuartii

- Amikacin, cefotaxime,[c] ceftriaxone,[c] fluoroquinolone[a,k]
- *Trimethoprim-sulfamethoxazole, aztreonam,[l] carbapenem*[g,h]

Pseudomonas aeruginosa

- UTI only
  - Aminoglycoside[i]
  - *Ciprofloxacin,[a] levofloxacin*[a]
- Systemic infection
  - Cefepime,[c] ceftazidime,[c] doripenem,[h] imipenem,[h] meropenem,[h] piperacillin-tazobactam, or ticarcillin-clavulanate + aminoglycoside[i]
  - *Aztreonam,[l] ciprofloxacin,[a] levofloxacin,[a] colistin*[h]

Salmonella typhi

- Ciprofloxacin,[a] levofloxacin,[a] ceftriaxone,[c] cefotaxime[c]
- *Trimethoprim-sulfamethoxazole*

Serratia marcescens

- Ceftriaxone,[c] cefotaxime,[c] cefepime,[c] ciprofloxacin,[a] levofloxacin[a]
- *Aztreonam,[l] carbapenem,[g,h] piperacillin-tazobactam, ticarcillin-clavulanate*

Stenotrophomonas (Xanthomonas) maltophilia (generally very resistant to all antimicrobials)

- Trimethoprim-sulfamethoxazole
- *Check sensitivities to ceftazidime,[c] doxycycline,[a] minocycline,[a] and ticarcillin-clavulanate*

MISCELLANEOUS MICROORGANISMS

Chlamydia pneumoniae

- Doxycycline[a]
- *Azithromycin, clarithromycin, erythromycin*, or *fluoroquinolone*[a,k]

Chlamydia trachomatis

- Azithromycin or doxycycline[a]
- *Levofloxacin,[a] erythomycin*

Mycoplasma pneumoniae

- Azithromycin, clarithromycin, erythromycin, fluoroquinolone[a,k]
- *Doxycycline*[a]

SPIROCHETES

Treponema pallidum

- Neurosyphilis
  - Penicillin G
  - *Ceftriaxone*[c]
- Primary or secondary
  - Benzathine penicillin G
  - *Ceftriaxone*[c] or *doxycycline*[a]

Borrelia burgdorferi (choice depends on stage of disease)

- Ceftriaxone[c] or cefuroxime axetil,[c] doxycycline,[a] amoxicillin
- *High-dose penicillin, cefotaxime*[c]

MIC, minimal inhibitory concentration; PO, orally

[a]Not for use in pregnant patients or children.

[b]First-generation cephalosporins—IV: cefazolin; PO: cephalexin, cephradine, or cefadroxil.

[c]Some penicillin-allergic patients may react to cephalosporins.

[d]Gentamicin should be added if tolerance or moderately susceptible (MIC >0.1 g/mL) organisms are encountered; streptomycin is used but can be more toxic.

[e]Second-generation cephalosporins—IV: cefuroxime; PO: cefaclor, cefditoren, cefprozil, cefuroxime axetil, and loracarbef.

[f]Third-generation cephalosporins—PO: cefdinir, cefixime, cefetamet, cefpodoxime proxetil, and ceftibuten.

[g]Carbapenem: doripenem, ertapenem, imipenem/cilastatin, meropenem.

[h]Reserve for serious infection.

[i]Aminoglycosides: gentamicin, tobramycin, and amikacin; use per sensitivities.

[j]β-lactam/β-lactamase inhibitor combination—IV: ampicillin-sulbactam, piperacillin-tazobactam, ticarcillin-clavulanate; PO: amoxicillin-clavulanate.

[k]Fluoroquinolones - IV/PO: ciprofloxacin, levofloxacin, and moxifloxacin.

[l]Generally reserved for patients with hypersensitivity reactions to penicillin.

This page intentionally left blank

CHAPTER 115

Central Nervous System Infections

ISAAC F. MITROPOULOS, ELIZABETH D. HERMSEN, AND JOHN C. ROTSCHAFER

KEY CONCEPTS

1. The three most likely pathogens of bacterial meningitis in the United States are *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Hemophilus influenzae*, although routine vaccination is having a dramatic effect on the incidence of these pathogens causing infection.
2. In cases of meningitis, initial findings can include (a) *presenting signs and symptoms*: fever, headache, nuchal rigidity (the classic triad), Brudzinski's or Kernig's sign, and altered mental status; and (b) *abnormal cerebrospinal fluid (CSF) chemistries*: elevated white blood cell (WBC) count (>100 cells/mm^3), elevated protein (>50 mg/dL), and decreased glucose levels (<40 mg/dL).
3. Two main microbiologic tests that should be obtained include a Gram stain and culture of the CSF.
4. Three primary goals of treatment in meningitis include (a) *eradication* of infection, (b) *amelioration* of signs and symptoms, and (c) *prevention* of the development of neurologic sequelae, such as seizures, deafness, coma, and death.
5. When selecting antibiotics, the clinician must consider the antibiotic concentration at the site of infection, as well as the spectrum of antibacterial activity. Empirical choices should be based on age, predisposing conditions, and comorbidities. (a) *Ceftriaxone* or *cefotaxime* and *vancomycin* are reasonable initial choices for empirical coverage of community-acquired meningitis in adult patients. (b) *Listeria monocytogenes* is a common pathogen in infants and elderly; therefore, *ampicillin* should be added empirically to antimicrobial coverage.
6. Empirical coverage with an appropriate antibiotic should be started as soon as possible when clinical suspicion of meningitis exists. If there is a delay in doing a lumbar puncture (even 30–60 minutes), or if the patient is to undergo neuroimaging, the first dose of an antibiotic *should not* be withheld. Changes in the CSF after initiation of antibiotics usually take 12 to 24 hours.
7. In contrast to the treatment of other infectious diseases, antibiotic dosages in the treatment of meningitis should be maximized to optimize CNS penetration.
8. The duration of antibiotic treatment for meningitis has not been standardized; however, the duration generally is based on the causative organism and the individual case and may range from 7 to 21 days.
9. Close contacts and relatives of the index case should be assessed for appropriate prophylaxis, particularly with *N. meningitidis* and *H. influenzae* meningitis.
10. Steroid treatment includes dexamethasone 0.15 mg/kg per dose to be given 4 times daily for 4 days in infants and children older than 2 months of age with proven or strongly suspected bacterial meningitis. Steroids should be given *prior* to antibiotics.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Central nervous system (CNS) infections are caused by a variety of pathogens, including bacteria, viruses, fungi, and parasites. Infections are the result of hematogenous spread from a primary infection site, seeding from a parameningeal focus, reactivation from a latent site, trauma, or congenital defects within the CNS. Newer diagnostic techniques have enabled more rapid and definitive diagnoses, thus diminishing the number of unknown "aseptic meningitis" diagnoses and improving targeted therapy. Bacteria resistant to multiple antibiotics present new challenges in the management of meningitis. This chapter presents the etiologies, pathophysiology, therapy, and prophylaxis of these infections but will concentrate predominantly on bacterial meningitis.

EPIDEMIOLOGY

Approximately 1.2 million cases of acute bacterial meningitis, excluding epidemics, occur every year around the globe, resulting in 135,000 deaths.[1] Overall mortality rates for patients with meningitis range from 2% to 30% depending on the causative microorganism, approaching 20% in most cases of bacterial meningitis.[2] Neurologic sequelae frequently associated with meningitis include seizures, sensorineural hearing loss, and hydrocephalus. Risk for the development of neurologic sequelae depends on the infecting organism, with pneumococcal meningitis being associated with the highest risk.[3] Generally, 30% to 50% of patients who survive meningitis may develop neurologic disabilities.[4,5] Despite the availability of antimicrobial therapy against the most common CNS pathogens, CNS infections continue to have significant morbidity and mortality.

Two findings that have the potential for great epidemiologic impact on bacterial meningitis are (a) passive and active exposures to cigarette smoke are risk factors for bacterial meningitis, especially meningococcal disease[6] and (b) children with cochlear

implants that include a positioner are at increased risk of bacterial meningitis, specifically pneumococcal meningitis. The incidence of meningitis due to *Streptococcus pneumoniae* in children with cochlear implants was more than 30 times the incidence in a similar cohort of the U.S. population without implants.[7]

ETIOLOGY

1 CNS infections are caused by a variety of microorganisms. Historically, CNS infections were primarily community acquired; however, an increasing number are now nosocomial.[8] *Hemophilus influenzae* was the most commonly identified cause of bacterial meningitis (45%), followed by *S. pneumoniae* (18%) and *Neisseria meningitidis* (14%). However, in 1995, approximately 5 years after introduction of the *H. influenzae* type b conjugate (Hib) vaccine, *S. pneumoniae* became the most commonly identified cause of bacterial meningitis (47%), followed by *N. meningitidis* (25%), group B streptococcus (13%), *Listeria monocytogenes* (8%), and *H. influenzae* (7%).

The incidence of invasive *H. influenzae* infections has decreased by more than 90% since the introduction of the Hib vaccine.[9] Mass immunization with the Hib vaccine also has resulted in alterations in the age distribution of bacterial meningitis. While the median age was 15 months in 1986, by 1995 that age increased to 25 years. Accordingly, the proportion of cases in those 18 years of age and older increased from 20.8% to 51.5%.[9] However, many developing countries have not adopted the Hib vaccine as part of the standard vaccines offered to children because of cost. Thus approximately 350,000 to 700,000 children die each year worldwide due to invasive *H. influenzae* infections.[1]

Following the release of the heptavalent protein-polysaccharide conjugate vaccine, the rate of invasive pneumococcal disease dropped from 24.3 cases per 100,000 people in 1999 to 17.3 per 100,000 in 2001. The largest impact was in children younger than 2 years of age where a nearly 70% decline in infection rate was reported as a result of implementation in the routine childhood vaccination schedule. Among children younger than 5 years of age, the rates of pneumococcal meningitis were reduced nearly 60% from 10.3 cases per 100,000 to 4.2 cases during the same time period. Interestingly, the effect carried into the adult population as well with significant reduction in invasive pneumococcal disease across all age groups.[10] Both the Hib and pneumococcal vaccines are of limited availability in developing countries where cost is often prohibitive.

ANATOMY AND PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM

MENINGES

The skull and vertebrae protect the CNS from blunt or penetrating trauma (Fig. 115–1). The brain is suspended in these structures by cerebrospinal fluid (CSF) and is surrounded by the meninges. The meninges are made up of three separate membranes: dura mater, arachnoid, and pia mater.[11] Dura mater, or pachymeninges, lies directly beneath and is adherent to the skull. The other two membranes are referred to collectively as *leptomeninges.* Pia mater lies directly over brain tissue. Arachnoid, the middle layer, lies between the dura mater and the pia mater. The subarachnoid space, located between the arachnoid and the pia mater, is the conduit for CSF. By definition, meningitis refers to inflammation of the subarachnoid space or spinal fluid, whereas encephalitis is an inflammation of the brain itself. Since infectious microorganisms frequently are an underlying cause of these inflammatory processes, the terms *meningitis* and *encephalitis* frequently are used to denote an infectious process. The decision regarding the diagnosis of meningoencephalitis depends on radiographic, laboratory, and clinical information but would refer to inflammation of both tissue and fluid.

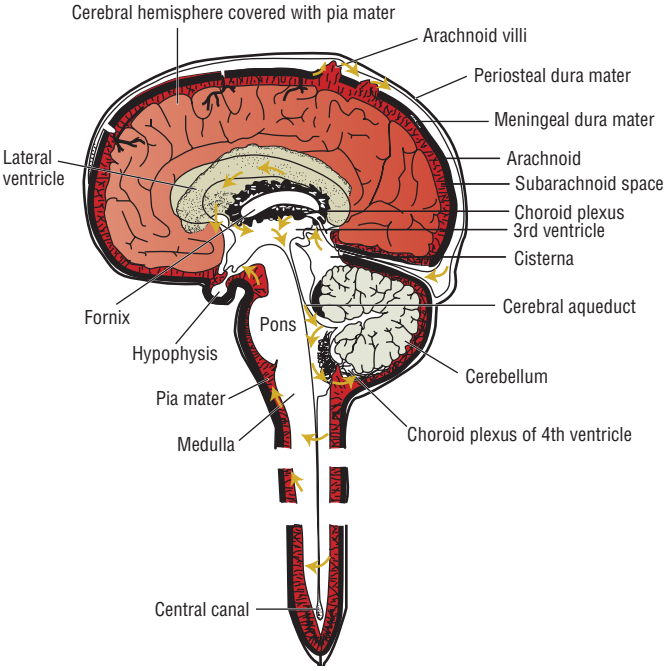

FIGURE 115-1. Diagram of the central nervous system.

CEREBROSPINAL FLUID

Approximately 85% of the CSF is produced within the third, fourth, and lateral ventricles by the choroid plexus (see Fig. 115–1). CSF volume in the CNS is related to patient age: Infants have approximately 40 to 60 mL of CSF, older children have 60 to 100 mL, and adults have 115 to 160 mL. Normally, CSF is produced at the rate of approximately 500 mL/day and flows unidirectionally downward through the spinal cord. The CSF is removed by the arachnoid villi and vertebral venous plexus located in the spinal cord and does not recommunicate with the point of production.[11]

The CSF normally is clear, with a protein content of less than 50 mg/dL, a glucose concentration of approximately 50% to 66% of the simultaneous peripheral serum glucose concentration, and a pH of approximately 7.4; also, it typically contains fewer than five white blood cells (WBCs) per cubic millimeter, all of which should be lymphocytes (Table 115–1). As meninges become inflamed, the constituency of the CSF will change, and these changes can be used diagnostically as markers of infection.

BLOOD–BRAIN BARRIER/ BLOOD–CSF BARRIER

Natural barriers to the exchange of drugs and endogenous compounds among the blood, brain, and CSF are the blood–brain barrier (BBB) and the blood–CSF barrier (BCSFB) (Fig. 115–2). The BBB consists of tightly joined capillary endothelial cells. Drug entry into brain tissue is accomplished by direct passage through the capillary endothelial cells and further penetration of the glial cells that envelop the capillary structure.[11]

TABLE 115-1 Mean Values of the Components of Normal and Abnormal Cerebrospinal Fluid[9,92]

Type	Normal	Bacterial	Viral	Fungal	Tuberculosis
WBC (cells/mm^3)	<5	1,000–5,000	100–1,000	40–400	100–500
Differential (%)	>90[a]	≥80 PMNs	50[b,c]	>50[b]	>80[b,c]
Protein (mg/dL)	<50	100–500	30–150	40–150	≤40–150
Glucose (mg/dL)	50%–66% simultaneous serum value	<40 (<60% simultaneous serum value)	<30–70	<30–70	<30–70

[a]Monocytes.
[b]Lymphocytes.
[c]Initial cerebrospinal fluid (CSF), while blood cell (WBC) count may reveal a predominance of polymorphonuclear neutrophils (PMNs).

Passage of drugs into the CSF is controlled by the BCSFB. This barrier is created by ependymal cells of the choroid plexus, which function as an active transport system similar to the renal tubular epithelial cells. The inflammatory process associated with meningitis inhibits the active transport system of the choroid plexus.[12] As in the active transport system in the kidney, the secretion of substances out of the choroid plexus also can be inhibited by the administration of probenecid.[11]

PATHOPHYSIOLOGY OF THE CNS INFECTION

The development of bacterial meningitis occurs following bacterial invasion of the host and CNS, bacterial multiplication with subsequent inflammation of the CNS, specifically the subarachnoid space and the ventricular space, pathophysiologic alterations owing to progressive inflammation, and the resulting neuronal damage.[13] The critical first step in the acquisition of acute bacterial meningitis is nasopharyngeal colonization of the host. Immunoglobulins (Igs) such as secretory IgA are found in high concentrations within nasopharyngeal secretions and work to inhibit bacterial colonization. However, the mucus barrier is deteriorated by IgA proteases secreted by the bacteria, which then extend pili that allow adherence to the host cell surface receptors.[14] Bacterial pathogens attach themselves to nasopharyngeal epithelial cells and are phagocytized into the host's bloodstream. After accessing the patient's bloodstream, bacteria must overcome the host's defense mechanisms.[1] Commonly, CNS bacterial pathogens will produce an extensive polysaccharide capsule resistant to neutrophil phagocytosis and complement opsonization. *H. influenzae*, *E. coli*, and *N. meningitidis* strains lacking polysaccharide capsules are unable to cause meningitis. Capsular polysaccharides activate the alternate complement pathway, which promotes phagocytosis and clearance of infecting pathogens. Patients unable to activate the alternative complement pathway, such as asplenic and sickle cell patients, are predisposed to bacterial infections caused by encapsulated microorganisms and therefore are at increased risk for meningitis.

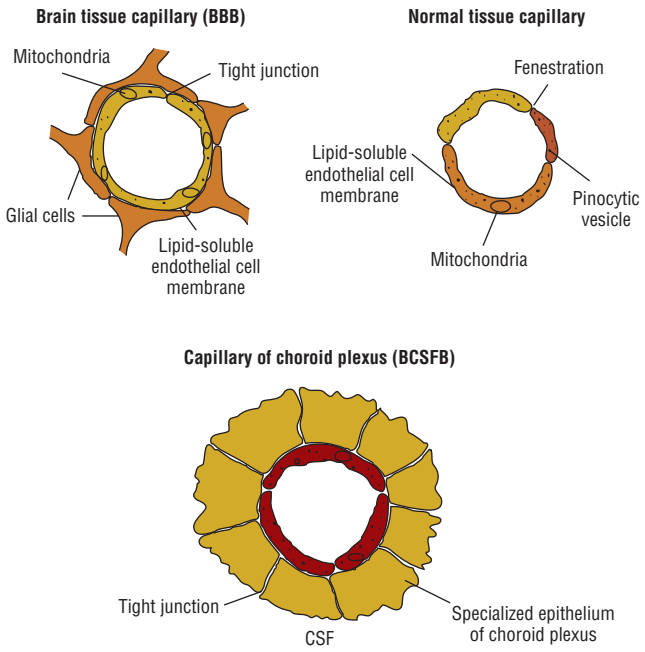

FIGURE 115-2. Schematic representation of a blood–cerebrospinal fluid barrier capillary, brain tissue capillary, and normal tissue capillary (*below*).

Although the exact site and mechanism of bacterial invasion into the CNS is unknown, studies suggest that invasion into the subarachnoid space occurs by continuous exposure of the CNS to large bacterial inocula. Bacteremia with inoculum densities of at least 10^3 colony-forming units (CFU)/mL appears to be essential for subarachnoid space invasion.[5] Although several sites of bacterial invasion have been theorized; the most plausible sites are the choroid plexus and/or the cerebral microvasculature. Successful translocation of *E. coli* across the BBB requires a high bacterial inoculum, *E. coli* binding to and invading the brain microvascular endothelial cells through specific ligand-receptor interactions, host cytoskeletal reorganization, and activation of various signaling pathways.[5] Host defense mechanisms within the subarachnoid space are inadequate to combat bacterial pathogens; bacteria, therefore, replicate freely within the CSF until either overgrowth occurs or an effective antibiotic regimen is administered that terminates the process.

The effects of meningitis, namely, inflammation within the subarachnoid space and the ensuing neurologic damage, are not necessarily a direct result of the pathogens themselves. The neurologic sequelae occur due to the activation of the host's inflammatory pathways, which is induced by the pathogens or their products.[2] Bacterial cell lysis and subsequent death can result in the release of cell wall components, such as lipopolysaccharide (LPS), lipid A (endotoxin), lipoteichoic acid, teichoic acid, and peptidoglycan, depending on whether the pathogen is gram-positive or gram-negative (Fig. 115–3). These cell wall components cause capillary endothelial cells and CNS macrophages to release cytokines (interleukin 1 [IL-1] and tumor necrosis factor [TNF]) and other inflammatory mediators (IL-6, IL-8, platelet-activating factor [PAF], nitric oxide, arachadonic acid metabolites [e.g., prostaglandin and prostacycline], and macrophage-derived proteins). Proteolytic products and toxic oxygen radicals are released from the capillary endothelium, causing an alteration in the permeability of the BBB. PAF activates the coagulation cascade, and arachidonic acid metabolites stimulate vasodilation. These events propagate other sequential events that lead to cerebral edema, elevated intracranial pressure (ICP), CSF pleocytosis, decreased cerebral blood flow, cerebral ischemia, and death.[2]

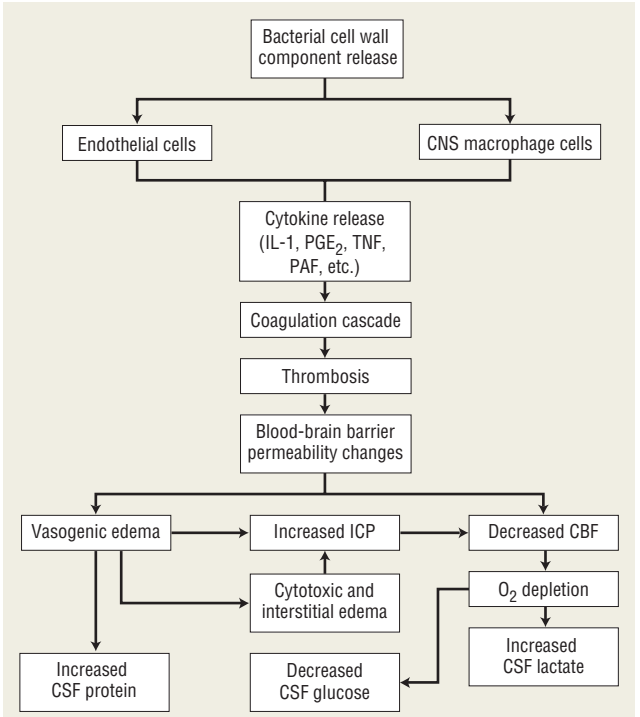

FIGURE 115-3. Hypothetical schema of pathophysiologic events that occur during bacterial meningitis. (IL-1, interleukin 1; TNF, tumor necrosis factor; PAF, platelet-activating factor; CBF, cerebral blood flow; CSF, cerebrospinal fluid; PGE_2, prostaglandin E_2; ICP, intracranial pressure.)

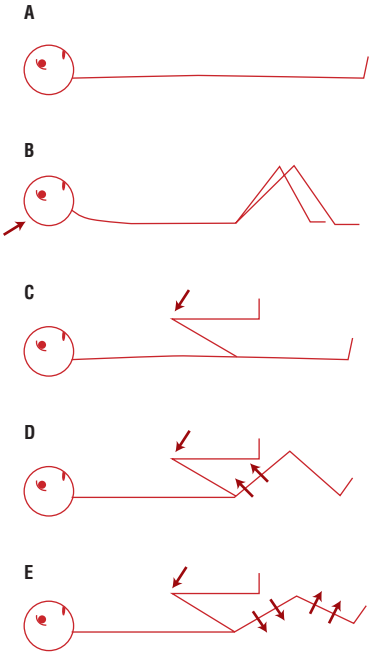

FIGURE 115-4. (*A,B*) Brudzinski's neck signs. Hip and knee flexion occurs as a result of flexion of the neck (*B*). (*C–E*) Brudzinski's leg signs. (*C*) Patient's leg is flexed by examiner (*arrow*). (*D*) The contralateral leg begins to flex—identical contralateral sign (*arrows*). (*E*) The contralateral leg now begins to extend spontaneously, resembling a little kick (*arrows*).

CLINCAL PRESENTATION AND DIAGNOSIS

CLINICAL PRESENTATION OF ACUTE MENINGITIS

General

- Clinical presentation varies with age, and generally, the younger the patient, the more atypical and the less pronounced is the clinical picture.
- Up to 50% of patients may receive antibiotics before a diagnosis of meningitis is made, delaying presentation to the hospital. Prior antibiotic therapy may cause the Gram stain and CSF culture to be negative, but the antibiotic therapy rarely affects CSF protein or glucose.[15]

Signs And Symptoms

- 2 Classic signs and symptoms include fever, nuchal rigidity, altered mental status (the classic triad), chills, vomiting, photophobia, and severe headache; Kernig's and Brudzinski's signs may also be present but are poorly sensitive and frequently are absent in children.[15,16] (Figs. 115–4 and 115–5).
- Other signs and symptoms include irritability, delirium, drowsiness, lethargy, and coma.
- Clinical signs and symptoms in young children may include bulging fontanelle, apneas, purpuric rash, and convulsions in addition to those just mentioned.[15]
- Seizures occur more commonly in children (20%–30%) than in adults (0%–12%).[17]

Differential Signs And Symptoms[2]

- Purpuric and petechial skin lesions typically indicate meningococcal involvement, although the lesions may be present with *H. influenzae* meningitis. Rashes rarely occur with pneumococcal meningitis.
- Waterhouse-Friderichsen syndrome, a rapid eruption of multiple hemorrhagic lesions associated with a shock-like state, is associated with meningococcal meningitis.
- *H. influenzae* meningitis and meningococcal meningitis both can cause involvement of the joints during the illness.
- A history of head trauma with or without skull fracture or presence of a chronically draining ear is associated with pneumococcal involvement.

Laboratory Tests

- Several tubes of CSF are collected via lumbar puncture for chemistry, microbiology, and hematology tests. Theoretically, the first tube has a higher likelihood of being contaminated with both blood and bacteria during the puncture, although the total volume is more important in practice than the tube cultured. CSF should not be refrigerated or stored on ice.[18]

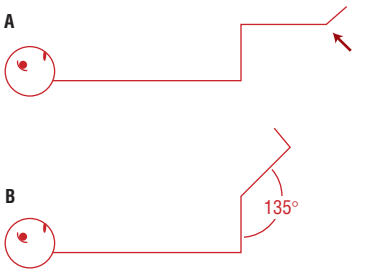

FIGURE 115-5. Kernig's sign. (*A*) Knees are raised to form a 90-degree angle relative to the trunk, and the examiner attempts to extend the knees. (*B*) Once the knee angle reaches approximately 135 degrees, contracture or extensor spasm occurs.

- Analysis of CSF chemistries typically includes measurement of glucose and total protein concentrations. An elevated CSF protein of ≥100 mg/dL and a CSF glucose concentration of less than 50% of the simultaneously obtained peripheral value suggest bacterial meningitis (see Table 115–1).
- The values for CSF glucose, protein, and WBC concentrations found with bacterial meningitis overlap significantly with those for viral, tuberculous, and fungal meningitis (see Table 115–1). Therefore, CSF WBC counts and CSF glucose and protein concentrations cannot always distinguish the different etiologies of meningitis.

Other Diagnostic Tests[18]

- In patients presenting with new-onset seizures, signs of space-occupying lesions or moderate to severe impairment of consciousness, cranial imaging via magnetic resonance imaging (MRI) or cranial computed tomography (CT) should precede a lumbar puncture. MRI is generally preferred as it more clearly identifies areas of cerebral edemas. In these instances, the withdrawal of CSF fluid from a lumbar puncture reduces counterpressure that may result in compression of the brain from above with risk of brain herniation complicating the clinical course.[19,20] Neuroimaging should not however delay initiation of antibiotic therapy as doing so can result in a poor outcome in this disease.[21]
- Blood and other specimens should be cultured according to clinical judgment because meningitis frequently can arise via hematogenous dissemination or can be associated with infections at other sites. A minimum of 20 mL of blood in each of two to three separate cultures per each 24-hour period is necessary for the detection of most bacteremias.
- 3 Gram stain and culture of the CSF are the most important laboratory tests performed for bacterial meningitis. The Gram stain continues to be the most rapid and accurate method of presumptively diagnosing acute bacterial meningitis. When performed before antibiotic therapy is initiated, Gram stain is both rapid and sensitive and can confirm the diagnosis of bacterial meningitis in 75% to 90% of cases. The sensitivity of the Gram stain decreases to 40% to 60% in patients who received prior antibiotic therapy. Culture is required to differentiate the various bacterial etiologies.
- Polymerase chain reaction (PCR) techniques can be used to diagnose meningitis caused by *N. meningitidis*, *S. pneumoniae*, and Hib. PCR is considered to be highly sensitive and specific, but use of this powerful diagnostic approach is limited due to expense and availability.
- Latex fixation, latex coagglutination, and enzyme immunoassay (EIA) tests provide for the rapid identification of several bacterial causes of meningitis, including *S. pneumoniae*, *N. meningitidis*, and Hib.[13] Rapid-identification latex tests work by bringing potential capsular antigens of the pathogen causing meningitis in contact with a specific antibody, causing an antigen-antibody reaction. This capsular antigen-antibody reaction can be observed visually and quickly without waiting for culture results. The rapid antigen tests should be used in situations in which the Gram stain is negative.[17] The sensitivity and specificity of latex fixation and coagglutination tests can vary with the manufacturer of the antibody, density of the antigen present in the CSF, and pathogen being tested.
- Diagnosis of tuberculosis meningitis employs acid-fast staining, culture, and PCR of the CSF.
- PCR testing of the CSF is the preferred method of diagnosing most viral meningitis infections.
- The standard diagnostic tests for fungal meningitis include culture, direct microscopic examination of stained and unstained specimens of CSF, antigen detection of cryptococcal or histoplasmal antigens, and antibody assay of serum and/or CSF.

TREATMENT

CNS Infections

DESIRED OUTCOME

Supportive care, particularly early in the course of treatment, is critically important. Administration of fluids, electrolytes, antipyretics, analgesics, and other supportive measures is indicated for patients presenting with acute bacterial meningitis. Although supportive care is important initially, appropriate antibiotic therapy (empirical or definitive) should be started as soon as possible. 4 Understanding antibiotic selection and the issues surrounding antibiotic penetration will assist in meeting the goals of treatment, which include eradication of infection with amelioration of signs and symptoms and prevention of neurologic sequelae, such as seizures, deafness, coma, and death.

APPROACH TO TREATMENT

This section discusses issues surrounding the approach to treatment, such as antibiotic penetration within the CNS, duration of antibiotic therapy, and the use of adjunctive corticosteroids. Until a pathogen is identified, prompt empirical antibiotic coverage is often needed. 5 Based on the patient's profile (i.e., allergies, age, and concurrent medical conditions), extent of antibiotic CNS penetration, and spectrum of activity, appropriate recommendations can be made, and therapy should last at least 48 to 72 hours or until the diagnosis of bacterial meningitis can be ruled out (Tables 115–2 and 115–3). 6 The first dose of antibiotics should not be withheld, even when lumbar puncture is delayed or neuroimaging is being performed. Changes in the CSF after antibiotic administration usually take 12 to 24 hours. Continued therapy should be based on the assessment of clinical improvement, cultures, and susceptibility testing results. Once a pathogen is identified, antibiotic therapy should be tailored to the specific pathogen (Tables 115–4 and 115–5). Throughout the course of treatment, efficacy parameters, such as signs and symptoms, microbiologic findings, and CSF examination, should be followed to evaluate the success of meeting the desired outcomes.

Several factors influence the transfer of antibiotic from capillary blood into the CNS, including inflammation of the meninges, which increases antibiotic penetration through damage to tight junctions between capillary endothelial cells and decreases the activity of an energy-dependent efflux pump in the choroid plexus responsible for movement of penicillins and, to a much lesser extent, fluoroquinolones and aminoglycosides (see Table 115–3). Antibiotics having low molecular weights are passed more easily through biologic barriers than compounds of higher molecular weight. Only antibiotics that are nonionized at physiologic or pathologic pH are capable of diffusion. Highly lipid-soluble compounds penetrate more readily than water-soluble compounds. Antibiotics not extensively protein bound in the serum provide a larger free fraction of drug capable of passing into the CSF. Passage

TABLE 115-2 Bacterial Meningitis: Most Likely and Empirical Therapy by Age Group

Age Commonly Affected	Most Likely Organisms	Empirical Therapy	Risk Factors for All Age Groups
Newborn–1 mo	Group B *Streptococcus* Gram-negative enterics[a] *Listeria monocytogenes*	Ampicillin + cefotaxime or ceftriaxone or aminoglycoside	Respiratory tract infection Otitis media Mastoiditis Head trauma Alcoholism High-dose steroids
1 mo–4 y	*S. pneumoniae* *N. meningitidis* *H. influenzae*	Vancomycin[b] and cefotaxime or ceftriaxone	Splenectomy Sickle cell disease Immunoglobulin deficiency
5–29 y	*N. meningitidis* *S. pneumoniae* *H. influenzae*	Vancomycin[b] and cefotaxime or ceftriaxone	Immunosuppression
30–60 y	*S. pneumoniae* *N. meningitidis*	Vancomycin[b] and cefotaxime or ceftriaxone	
>60 y	*S. pneumoniae* Gram-negative enterics *L. monocytogenes*	Vancomycin[b] plus ampicillin plus cefotaxime or ceftriaxone	

[a] *E. coli*, *Klebsiella* spp, *Enterobacter* spp common.
[b] Vancomycin use should be based on local incidence of penicillin-resistant *S. pneumoniae* and until cefotaxime or ceftriaxone minimum inhibitory concentration results are available.

TABLE 115-3 Penetration of Antimicrobial Agents into the Cerebrospinal Fluid

Therapeutic levels in CSF with or without inflammation	
Choramphenicol	Pyrazinamide
Cycloserine	Rifampin
Ethionamide	Sulfonamides
Isoniazid	Trimethoprim
Metronidazole	
Therapeutic levels in CSF with inflammation of meninges	
Acyclovir	Ganciclovir
Ampicillin ± sulbactam	Imipenem
Aztreonam	Levofloxacin
Carbenicillin	Linezolid
Cefotaxime	Meropenem
Ceftazidime	Mezlocillin
Ceftizoxime	Moxifloxacin
Ceftriaxone	Nafcillin
Cefuroxime	Ofloxacin
Ciprofloxacin	Penicillin G
Colistin	Piperacillin
Daptomycin	Pyrimethamine
Ethambutol	Quinupristin/dalfopristin
Fluconazole	Ticarcillin ± clavulanic acid
Flucytosine	Vancomycin
Foscarnet	Vidarabine
Non-therapeutic levels in CSF with or without inflammation	
Aminoglycosides	Cephalosporins (Second Generation)[a]
Amphotericin B	Clindamycin[b]
Cefoperazone	Itraconazole[c]
Cephalosporins (first generation)	Ketoconazole

[a] Cefuroxime is an exception.
[b] Achieves therapeutic brain tissue concentrations.
[c] Achieves therapeutic concentrations for *Cryptococcus neoformans* therapy.
CSF, cerebrospinal fluid.

of large, polar antibiotics into the CSF may be assisted, however, by a carrier transport system. 7 Unlike the treatment of many other infections, antibiotic dosages in the treatment of CNS infections must be maximized to optimize penetration to the site of infection.

Problems of CSF penetration may be overcome by direct instillation of antibiotics intrathecally, intracisternally, or intraventricularly (Table 115–6). Advantages of direct instillation, however, must be weighed against the risks of invasive CNS procedures. Intrathecal administration of antibiotics is unlikely to produce therapeutic concentrations in the ventricles possibly owing to the unidirectional flow of CSF.[22] Although intraventricular administration from a therapeutic standpoint may be preferred over intrathecal administration, the former requires neurosurgical placement of a subcutaneous reservoir. Intraventricular delivery may be necessary when bacteria that require treatment with aminoglycosides, such as *L. monocytogenes, Pseudomonas aeruginosa* or enterococci, are isolated. Children who received both parenteral antibiotics and intrathecal gentamicin had higher CSF endotoxin levels, higher CSF IL-1β levels, and higher mortality than children receiving only parenteral antibiotics. Interestingly, the differences were attributed to direct CSF administration of gentamicin, which generally is thought to blunt the endotoxin release caused by β-lactam antibiotics.[23]

8 Although the length of treatment for bacterial meningitis generally is based on the causative organism, there is no universally accepted standard (Table 115–4). Meningitis caused by *S. pneumoniae* has been treated successfully with 10 to 14 days of antibiotic therapy. Meningitis caused by *N. meningitidis* usually can be treated with a 7-day course of antibiotics. In contrast, a longer duration (≥21 days) has been recommended for patients infected with *L. monocytogenes* (A-III). Therapy should be individualized, and some patients may require enduring courses.

CAUSATIVE AGENTS

N. Meningitidis (Meningococcus)

N. meningitidis is the leading cause of bacterial meningitis in children and young adults in the United States.[24] The source of infection usually is an asymptomatic carrier. Most cases occur in the winter or spring, a time when viral meningitis is relatively uncommon. Five serogroups of *N. meningitidis* (A, B, C, Y, and W-135) are primarily responsible. Clusters of meningococcal disease, defined as two or more cases of the same serogroup that are closer in time and space than expected for the population or group under observation, generally are associated with schools.[25] Although some of these clusters have been due to serogroup B, the majority have been due to serogroup C. Serogroup A, although associated with meningococcal outbreaks in Africa and Asia, is a rare cause of disease in the United States.[26] Serogroup Y, although frequently associated with pneumonia, is emerging as an important cause of invasive meningococcal disease in select areas.[27,28] Overall, *N. meningitidis* accounts for 25% of all meningitis cases, 60% of cases in persons aged 2 to 18 years, and carries a case-fatality rate of approximately 10%.[9,27]

Initially, patients are colonized and, at some point, develop a bacteremia, which most likely occurs prior to hospital admission. Meningitis occurs after the bacteria seeds into the meninges, which can occur in 50% of the cases of meningococcal disease.[29] After the acute phase of meningitis has resolved, there is a unique immune reaction that distinguishes meningococcal meningitis from other bacterial causes. The patient develops a characteristic immunologic reaction of fever, arthritis (usually involving large joints), and pericarditis approximately 10 to 14 days after the onset of disease

TABLE 115-4 Antimicrobial Agents of First Choice and Alternative Choice in the Treatment of Meningitis Caused by Gram-Positive and Gram-Negative Microorganisms

Organism	Antibiotic of First Choice	Alternative Antibiotics	Recommended Duration of Therapy
Gram-positive			
Streptococcus pneumoniae			10–14 days
Penicillin susceptible	Penicillin G or Ampicillin (A-III)	Cefotaxime (A-III), Ceftriaxone (A-III), Chloramphenicol (A-III)	
Penicillin intermediate	Cefotaxime or Ceftriaxone (A-III)	Cefepime (B-II), Meropenem (B-II), Moxifloxacin (B-II), Linezolid (C-III)	
Penicillin resistant	Vancomycin[a] plus Cefotaxime or Ceftriaxone (A-III)	Cefepime (B-II), Meropenem (B-II), Moxifloxacin (B-II), Linezolid (C-III)	
Group B *Streptococcus*	Penicillin G or Ampicillin ± Gentamicin[a] (A-III)	Cefotaxime (B-III), Ceftriaxone (B-III), Chloramphenicol (B-III)	14–21 days
Staphylococcus aureus			14–21 days[e]
Methicillin susceptible	Nafcillin or Oxacillin (A-III)	Vancomycin[a] (A-III), Meropenem (B-III)	
Methicillin resistant	Vancomycin[a] (A-III)	Trimethoprim-sulfamethoxazole (A-III), Linezolid (B-III)	
Staphylococcus epidermidis	Vancomycin[a] (A-III)	Linezolid (B-III)	14–21 days[e]
Listeria monocytogenes	Penicillin G or Ampicillin ± Gentamicin[a] (A-III)	Trimethoprim-sulfamethoxazole (A-III), Meropenem (B-III)	≥21 days
Gram-negative			
Neisseria meningitis			7 days
Penicillin susceptible	Penicillin G or Ampicillin (A-III)	Cefotaxime (A-III), Ceftriaxone (A-III), Chloramphenicol (A-III)	
Penicillin resistant	Cefotaxime or Ceftriaxone (A-III)	Chloramphenicol (A-III), Meropenem (A-III), Fluoroquinolone (A-III)	
Haemophilus influenzae			7 days
β-Lactamase negative	Ampicillin (A-III)	Cefotaxime (A-III), Ceftriaxone (A-III), Chloramphenicol (A-III), Cefepime (A-III), Fluoroquinolone (A-III)	
β-Lactamase positive	Cefotaxime or Ceftriaxone (A-I)	Cefepime (A-I), Fluoroquinolone (A-III), Chloramphenicol (A-III)	
Enterobacteriaceae[d]	Cefotaxime or Ceftriaxone (A-II)	Cefepime (A-III), Fluoroquinolone (A-III), Meropenem (A-III), Aztreonam (A-III)	21 days
Pseudomonas aeruginosa	Cefepime or Ceftazidime (A-II) ± Tobramycin[a,b] (A-III)	Ciprofloxacin (A-III), Meropenem (A-III), Piperacillin plus Tobramycin[a,b] (A-III), Colistin sulfomethate[a,c] (B-III), Aztreonam (A-III)	21 days

Strength of recommendation: (A) Good evidence to support a recommendation for use; should always be offered. (B) Moderate evidence to support a recommendation for use; should generally be offered.

Quality of evidence: (I) Evidence from ≥1 properly randomized, controlled trial. (II) Evidence from ≥1 well-designed clinical trial, without randomization; from cohort or case-controlled analytic studies (preferably from >1 center) or from multiple time-series. (III) Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

[a] Monitor drug levels in serum.

[b] Direct central nervous system administration may be added; see Table 115–6 for dosage.

[c] Should be reserved for multidrug-resistant pseudomonal or *Actinetobacter* infections for which all other therapeutic options have been exhausted.

[d] Includes *E. coli* and *Klebsiella* spp.

[e] Based on clinical experience; no clear recommendations.

and despite successful treatment.[30] At this time, examination of the synovial fluid reveals a large number of polymorphonuclear cells, elevated protein concentrations, normal glucose concentrations, and sterile cultures. The reaction may last a week or longer, and no additional antibiotic therapy is required. Patients, however, may benefit from nonsteroidal antiinflammatory agents and supportive care.[30]

Seizures and coma are uncommon with meningococcal meningitis. Patients may behave aggressively, however, and often are maniacal. Patients may develop deafness and transiently impaired ocular movements. Deafness unilaterally or, more commonly, bilaterally may develop early or late in the disease course.[30] Hearing loss secondary to sensory nerve damage (sensorineural hearing) is usually permanent, whereas conductive hearing impairment, such as damage to the tympanic membrane, is often reversible.

The presence of petechiae may be the primary clue that the underlying pathogen is *N. meningitidis*. Approximately 50% of patients with meningococcal meningitis have purpuric lesions, petechiae, or both. Patients may have an obvious or subclinical picture of disseminated intravascular coagulation (DIC), which may progress to infarction of the adrenal glands and renal cortex and cause widespread thrombosis.

Aggressive, early intervention with high-dose intravenous crystalline penicillin G, 50,000 units/kg every 4 hours, is usually recommended for the treatment of *N. meningitidis* meningitis. Chloramphenicol is bactericidal for *N. meningitidis* and may be used in place of penicillin G. However, chloramphenicol has unpredictable metabolism in young infants and several drug–drug interactions which largely preclude its use in developed countries.[2] Several third-generation cephalosporins (i.e., cefotaxime, ceftriaxone, ceftazidime and ceftizoxime) have indications for the treatment of meningitis and are acceptable alternatives to penicillin G (see Table 115–5). Meropenem and fluoroquinolones are also suitable alternatives for the treatment of penicillin nonsusceptible meningiococci (A-III).

Cases of meningitis caused by relatively penicillin-resistant meningococci (minimun inhibitory concentration [MIC] 0.1–1 mg/L) and highly (MIC ≥ 256 mg/L) have been reported. Prevalence varies geographically, ranging from 0.4% to 42.6%.[31] Isolated reports of treatment failure with penicillin have surfaced in recent years.[32,33] Completely resistant strains produce β-lactamase, whereas relatively resistant strains have an alteration of penicillin-binding proteins. The emergence of β-lactamase producing strains of meningococci are causing more practitioners to utilize third-generation cephalosporins (cefotaxime or ceftriaxone) instead of penicillin, which has long been considered the drug of choice for meningococcal meningitis.[34]

N. meningitidis is spread by direct person-to-person close contact, including respiratory droplets and pharyngeal secretions.[29] Close contacts of patients contracting *N. meningitidis* meningitis are at an increased risk of developing meningitis. Close contacts include day-care center contacts, members of the household, or anyone who has been exposed to respiratory or oral secretions through activities such as coughing, sneezing, or kissing. Household contacts of people who have sporadic disease are estimated to have an incidence of meningococcal meningitis that is 500 to 800 times

TABLE 115-5 Dosing of Antimicrobial Agents by Age Group

Antimicrobial Agent	Infants and Children	Adults
Antibacterials		
Ampicillin	75 mg/kg every 6 h	2 g every 4 h
Aztreonam		2 g every 6–8 h
Cefepime	50 mg/kg every 8 h	2 g every 8 h
Cefotaxime	75 mg/kg every 6–8 h	2 g every 4–6 h
Ceftazidime	50 mg/kg every 8 h	2 g every 8 h
Ceftriaxone	100 mg/kg once daily	2 g every 12–24 h
Chloramphenicol	25 mg/kg every 6 h	1–1.5 g every 6 h
Ciprofloxacin	10 mg/kg every 8 h	400 mg every 8–12 h
Colistin[a,c]	5 mg/kg once daily	5 mg/kg once daily
Gentamicin[a,b]	2.5 mg/kg every 8 h	2 mg/kg every 8 h
Levofloxacin	10 mg/kg once daily	750 mg once daily
Linezolid	10 mg/kg every 8 h	600 mg every 12 h
Meropenem	40 mg/kg every 8 h	2 g every 8 h
Moxifloxacin		400 mg once daily
Oxacillin/Nafcillin	50 mg/kg every 6 h	2 g every 4 h
Penicillin G	0.05 mUnits/kg every 4–6 h	4 mUnits every 4 h
Piperacillin	50 mg/kg every 4–6 h	3 g every 4–6 h
Tobramycin[a,b]	2.5 mg/kg every 8 h	2 mg/kg every 8 h
TMP-SMZ[d]	5 mg/kg every 6–12 h	5 mg/kg every 6–12 h
Vancomycin[a]	15 mg/kg every 6 h	15 mg/kg every 8–12 h
Antimycobacterials		
Isoniazid[e]	10–15 mg/kg once daily	5 mg/kg once daily
Rifampin	10–20 mg/kg once daily	600 mg once daily
Pyrazinamide	15–30 mg/kg once daily	15–30 mg/kg once daily
Ethambutol	15–25 mg/kg once daily	15–2 5mg/kg once daily
Antifungals		
Amphotericin B		0.7–1 mg/kg once daily
Lipid amphotericin B		4 mg/kg once daily
Flucytosine		25 mg/kg every 6 h
Fluconazole		400–800 mg once daily
Voriconazole		6 mg/kg every 12 h × 2 doses then 4 mg/kg every 12 h
Antivirals		
Acyclovir	20 mg/kg every 8 h	10 mg/kg every 8 h
Foscarnet		60 mg/kg every 8–12 h

[a]Monitor drug levels in serum.
[b]Direct central nervous system administration may be added; see Table 115–6 for dosage.
[c]Should be reserved for multidrug-resistant pseudomonal or *Actinetobacter* infections for which all other therapeutic options have been exhausted.
[d]Dosing based on trimethoprim component.
[e]Supplemental pyridoxine hydrochloride (vitamin B_6) 50 mg/day is recommended.

TABLE 115-6 Intraventricular and Intrathecal Antibiotic Dosage Recommendation

Antibiotic	Dose (mg)	Expected CSF Concentration[a] (mg/L)	Reference
Ampicillin	10–50	60–300	114–116
Methicillin	25–100	160–600	114–116
Nafcillin	75	500	115
Cephalothin	25–100	160–600	114–116
Chloramphenicol	25–100	160–600	114, 116, 117
Gentamicin	1–10	6–60	114–118
Quinupristin/dalfopristin	1–2	7–13	119
Tobramycin	1–10	6–60	118
Vancomycin	5	30	120–122
Amphotericin B	0.05–0.25 mg/day or 0.05–1 mg 1–3 times weekly	–	123

[a]Assumes adult CSF volume = 150 mL.
CSF, cerebrospinal fluid.

greater than that of the overall population.[29] Secondary cases of meningitis usually develop within the first week following exposure, but they may take up to 60 days after contact with the index case.[35] Young children are at the greatest risk of contracting *N. meningitidis;* however, all ages are at risk, especially close contacts exposed via household, daycare, or military contact.

9 Prophylaxis of close contacts should be started only after consultation with the local health department. In general, rifampin is given as prophylaxis for 2 days.[26] The adult dose is 600 mg every 12 hours, whereas children aged 1 month and older should receive 10 mg/kg every 12 hours, and children younger than 1 month should receive 5 mg/kg every 12 hours (A-III). Intramuscular ceftriaxone (250 mg in adults, 125 mg in children younger than 12 years of age) and oral ciprofloxacin (500 mg in adults and children older than 12 years) are alternatives to rifampin (A-III).[15] Further discussion of who should receive prophylaxis is beyond the scope of this chapter; interested readers can refer to the recommendations of the U.S. Centers for Disease Control and Prevention for that information.[36]

S. Pneumoniae (Pneumococcus or Diplococcus)

S. pneumoniae is the leading cause of meningitis in adults. Moreover, *S. pneumoniae* is the most common cause of bacterial meningitis in children younger than 2 years of age, accounting for 4 to 6 cases per 100,000 of this population, and the second most common cause in children older than 2 years of age.[37] Case-fatality rates in children are highest with this organism and approach 20%. Approximately 50% of cases are secondary infections resulting from primary infections of parameningeal foci, such as the ear or paranasal sinuses. Pneumonia, endocarditis, CSF leak secondary to head trauma, splenectomy, alcoholism, sickle cell disease, and bone marrow transplantation may predispose the patient to the development of pneumococcal meningitis.

Neurologic complications, such as coma and seizures, are common with pneumococcal meningitis. Children with pneumococcal meningitis have lower mortality rates (4%–17%) compared with the mortality rates in adults (20%–30%), but children who survive suffer from a high rate of neurologic sequelae (29%–56%).[38,39] Risk factors for recurrent pneumococcal meningitis include traumatic tears of the dura, fracture of the cribriform plate or paranasal sinuses, nasal meningoceles, repeated episodes of otitis media, basilar skull fractures, and CSF leaks. The prognosis of pneumococcal meningitis depends on a variety of factors, including the number of WBCs in the CSF, the number of WBCs in the periphery, the CSF glucose concentration, the CSF protein concentration, the serum sodium concentration, and the presence of a comatose state and/or shock.[40]

Based on resistance patterns and the fact that sufficient CSF concentrations of penicillin are difficult to achieve with standard intravenous doses, penicillin should not be used as empirical therapy if *S. pneumoniae* is a suspected pathogen. Furthermore, appropriate Clinical Laboratory Standards Institute (CLSI)-approved testing of all CSF isolates for penicillin resistance is recommended. Ceftriaxone and cefotaxime have served as alternatives to penicillin in the treatment of penicillin intermediate- and high-resistant pneumococci. Of note, treatment failures with third-generation cephalosporins in the management of penicillin-resistant pneumococci have been reported.[34] Therapeutic approaches to cephalosporin-resistant pneumococcus include the addition of vancomycin and rifampin, which have demonstrated synergistic activity with ceftriaxone. However, no data from controlled clinical

trials supporting the use of rifampin are available. Therefore, the combination of vancomycin and ceftriaxone has been suggested as empirical treatment until the results of antimicrobial susceptibility testing are available.[2,34] Some investigators have suggested that the addition of vancomycin to the initial empirical regimen may not be necessary because the prevalence of β-lactam–resistant pneumococci has been reduced greatly as a result of the pneumococcal vaccines.[2]

Ceftriaxone and vancomycin are the agents of choice to treat presumed pneumococcal meningitis empirically until the susceptibility is known. Penicillin may be used for drug-susceptible isolates with MICs of 0.06 mg/L or less, but for intermediate isolates, ceftriaxone is used, and for highly drug resistant isolates, a combination of ceftriaxone and vancomycin should be used. Vancomycin should not be used as monotherapy.[34] In severe cases, therapeutic drug monitoring of the CSF and possibly even direct antibiotic instillation may be necessary.

Some pneumococcal strains exhibit tolerance to vancomycin and are of great concern, but the clinical significance is unknown.[41,42] Based on concern about the limited therapeutic options for penicillin- and cephalosporin-resistant pneumococcal meningitis, newer agents have been evaluated. Meropenem is approved by the U.S. Food and Drug Administration (FDA) for the treatment of bacterial meningitis in children aged 3 months and older and has shown similar clinical and microbiologic efficacy to cefotaxime or ceftriaxone. Meropenem is currently recommended as an alternative to a third generation cephalosporin in penicillin nonsusceptible isolates (B-II). Some caution is warranted with the use of imipenem for CNS infections because of the possibility of drug-induced seizures, especially when not properly dose adjusted for declining renal function. Of note, seizures may be caused by meningitis itself or by imipenem, and the cause is difficult to differentiate. The newer fluoroquinolones represent another therapeutic option owing to favorable activity against multidrug-resistant pneumococci and good penetration into the CSF.[43] However, clinical data to date regarding fluoroquinolone treatment of pneumococcal meningitis are limited mainly to animal models. Comparative, controlled clinical efficacy trials in patients with meningitis will be necessary before routine use of the fluoroquinolones is viable.

Linezolid, and daptomycin have emerged as therapeutic options for treating multidrug-resistant gram-positive infections. Linezolid in combination with ceftriaxone has been used to treat a limited number of cases of pneumococcal meningitis with outcomes similar to standard treatment.[44] The penetration of daptomycin in the CSF was approximately 6% following a 15mg/kg bolus achieving maximum concentration approximately four hours after the dose in a rabbit meningitis model. The 15 mg/kg dose produces similar serum concentrations in rabbits as the 6 mg/kg dose in humans. In this study, daptomycin was able to clear both the penicillin-resistant and the quinilone-resistant pneumococci from the CSF more rapidly than the standard regimen of vancomycin and ceftriaxone.[45] Additionally, daptomycin may reduce the inflammatory response caused by cell wall components in pneumococcal meningitis compared with ceftriaxone.[46] However, limited data are available, and these agents cannot be recommended for use in the treatment of pneumococcal meningitis.

CLINICAL CONTROVERSY

Some investigators believe that the use of vancomycin in the empirical treatment of pneumococcal meningitis is no longer necessary because the widespread use of pneumococcal vaccines has greatly reduced the prevalence of β-lactam–resistant pneumococci. However, because the infecting organism is rarely known initially, most clinicians still use the combination of a third-generation cephalosporin and vancomycin for empirical treatment.

Pneumococcal vaccines help in reducing the risk of invasive pneumococcal disease. Virtually all serotypes of *S. pneumoniae* exhibiting intermediate or complete resistance to penicillin are found in the 23-serotype pneumococcal polysaccharide vaccine. However, in 1997, only 30% of people 65 years of age and older had been immunized against pneumococcal disease.[47] Therefore, the CDC issued stronger recommendations for the use of the pneumococcal polysaccharide vaccine, calling for vaccination of the following high-risk groups: persons over the age of 65 years; persons aged 2 to 64 years who have a chronic illness, who live in high-risk environments (e.g., Alaskan Natives and residents of long-term care facilities), and who lack a functioning spleen (e.g., sickle cell disease and splenectomy); and immunocompromised persons over the age of 2 years, including those with HIV infection. Additionally, the question of whether or not college students living in dormitories, a possible high-risk environment, should be vaccinated remains debatable. Unfortunately, variability in the host's ability to mount an immune response to the vaccine limits its usefulness for penicillin-resistant pneumococci in children younger than 2 years of age and in immunocompromised adults.

In 2000, a heptavalent pneumococcal conjugate vaccine (Prevnar) was approved for use in children 2 months of age and older. Use of the vaccine has reduced invasive pneumococcal infections, including sepsis and meningitis more than 90%.[48] Moreover, the vaccine is safe and effective in low-birth-weight and preterm infants.[49,50] Widespread vaccination is expected to have a significant impact on the prevalence of pneumococcal meningitis, including infection caused by antibiotic-resistant strains. A cohort study of 3.8 million healthy infants projected that vaccination would prevent more than 12,000 cases of invasive disease for each U.S. birth cohort, resulting in substantial decreases in morbidity and mortality, as well as possible cost savings.[51] Current recommendations are for all healthy infants younger than 2 years of age to be immunized with the heptavalent vaccine at 2, 4, 6, and 12 to 15 months. The recommendations are extended to include Alaskan Native, Native American, and African American children between the ages of 2 and 5 years. The CDC has issued a recommendation that all persons with cochlear implants receive age-appropriate vaccination with the pneumococcal conjugate vaccine, pneumococcal polysaccharide vaccine, or both.[52]

H. Influenzae

Historically, *H. influenzae* was the most common cause of meningitis in children 6 months to 3 years of age. Since the introduction of effective vaccines, however, the incidence of *H. influenzae* type B disease in the United States has declined dramatically. Widespread vaccination of infants and children has decreased the incidence of bacterial meningitis due to *H. influenzae* in children between the ages of 1 month and 5 years by 87%, resulting in a 55% decline in all cases of bacterial meningitis.[14] Worldwide, in countries that have adopted universal immunization, the incidence of bacterial meningitis caused by *H. influenzae* type b has decreased more than 99%.[2] In children older than 3 years and adults, meningitis caused by *H. influenzae* may indicate a parameningeal focus of infection such as middle ear infection, paranasal sinus infection, or CSF leakage. Spread of the organism occurs either through direct spread from infected sinuses, draining of these areas via the veins, or bacteremia originating from the local focus of infection.[53]

Since approximately 30% to 40% of *H. influenzae* are now ampicillin-resistant, a third-generation cephalosporin is recommended empirically until sensitivities are available. If the organism is then sensitive to ampicillin, the patient can be switched to ampicillin and the the cephalosporin discontinued (A-1). Third-generation cephalosporins (cefotaxime and ceftriaxone) are active against β-lactamase–producing and non–β-lactamase–producing strains of *H. influenzae.* In addition, they are relatively free of toxicity, and do not require serum concentration monitoring. Cefepime (A-I) and fluoroquinolones (A-III) are suitable alternatives regardless of β-lactamase activity.

Secondary cases resulting from close contact with an index case occur within 30 days of the onset of disease. Close contacts, which include household members, individuals sharing sleeping quarters, daycare attendees, nursing home residents, and crowded, confined populations, may be at 200 to 1,000 times the risk of the general population for acquiring *H. influenzae* meningitis. The risk of acquiring *H. influenzae* meningitis is low without intimate contact with the index patient's respiratory secretions.[54]

9 Prophylaxis is to protect close contacts from the index case by eliminating nasopharyngeal and oropharyngeal carriage of *H. influenzae*. Invasive disease should be reported to the local public health department and the CDC. Prophylaxis of close contacts should be started only after consultation with the local health department. In general, children should receive rifampin 20 mg/kg per day (maximum 600 mg) and adults 600 mg/day in one dose for 4 days. Any unvaccinated children between the ages of 12 and 48 months should receive one dose of the vaccine, whereas those between the ages of 2 and 11 months should be given three doses of the vaccine.[15] Individuals fully vaccinated are not recommended to receive prophylaxis.[26] Further discussion of who should receive prophylaxis is beyond the scope of this chapter; interested readers can refer to the recommendations of the American Academy of Pediatrics for that information.[55]

Vaccination includes a series of doses and usually is begun in children at 2 months of age. The DTaP/Hib combination vaccine (diphtheria, tetanus, acellular pertusis, *H. influenzae* type B) is also available as a booster following the Hib series. In addition to pediatric immunization, the vaccine also should be considered in patients older than 5 years of age with the following underlying conditions: sickle cell disease, asplenia, and immunocompromising diseases. Refer to Chapter 133 for further information on dosing and administration.

L. Monocytogenes

L. monocytogenes is a gram-positive diphtheroid-like organism responsible for 8% of all reported cases of meningitis. This disease primarily affects neonates, alcoholics, immunocompromised adults, and the elderly. Infections caused by *Listeria* in healthy individuals are extremely rare. *L. monocytogenes* is implicated in 20% of meningitis cases in those older than 60 years of age and carries a case-fatality rate of approximately 15%.[9]

Transmission usually involves colonization of the patient's gastrointestinal (GI) tract with the organisms, which then penetrate the gut lumen. Coleslaw, unpasteurized milk, Mexican-style soft cheese, ready-to-eat foods, and raw beef and poultry all have been identified as sources of this food-borne pathogen.[26] If a sufficient cell-mediated immune response (T-lymphocytes, macrophages) is not produced, bacteremia, meningitis, meningoencephalitis, or cerebritis may develop. Infection of the CNS may be diffuse or localized, possibly involving the cerebral hemispheres, thalamus, and brain stem. In immunocompromised hosts, approximately 75% of *L. monocytogenes* infections result in transmission into the CNS.[56]

Incidence of *L. monocytogenes* meningitis tends to peak in the summer and early fall. As with gram-negative meningitis, presentation may be subtle and insidious, and clinical suspicion should prompt lumbar puncture. *L. monocytogenes* produces primarily a mononuclear CSF response.[56] One common laboratory error seen with *L. monocytogenes* is a tendency to misidentify the organism on Gram stain as a diphtheroid, streptococcus, or a poorly staining gram-negative rod.

Treatment of *L. monocytogenes* meningitis with penicillin G or ampicillin may result in only a bacteriostatic effect and possible persistence of infection. Usually the combination of penicillin G or ampicillin with an aminoglycoside results in a bactericidal effect. Patients should be treated for 2 to 3 weeks after defervescence (A-III).[15] Combination therapy is usually employed for a minimum of 10 days, with the remaining course of therapy completed with penicillin G or ampicillin alone. Trimethoprim-sulfamethoxazole may be an effective alternative because adequate CSF penetration is achieved (A-III). Chloramphenicol and vancomycin both possess in vitro activity against *Listeria*, but they are not be recommended for use in meningitis caused by *L. monocytogenes* owing to unacceptably high failure rates.[34]

Gram-Negative Meningitis

During the last several years, the incidence of gram-negative bacillary meningitis, excluding *H. influenzae,* has been increasing in both children and adults. Enteric gram-negative organisms are the fourth leading cause of meningitis, with only *S. pneumoniae*, *H. influenzae*, and *N. meningitidis* having a higher incidence.

Several factors predispose patients to the development of gram-negative meningitis: congenital defects involving the CNS, accidental cranial trauma, neurosurgery, the use of antimicrobial agents with exclusive gram-positive activity preoperatively in neurosurgery, any form of communication between the skin and subarachnoid space (such as a dermal sinus), diabetes, malignancy, urinary tract infection in neonates, cirrhosis, parameningeal infection, spinal anesthesia, advanced age, immunosuppression, and hospitalization in general.

Elderly debilitated patients are at an increased risk of gram-negative meningitis but typically lack the classic signs and symptoms of the disease. Nuchal rigidity may be difficult to detect secondary to cervical arthritis. Presence of a low-grade fever and changes in mental status without other obvious cause should prompt consideration of meningitis and a lumbar puncture. Neonates are also at risk for gram-negative meningitis with *E. coli* and *Klebsiella pneumoniae*, which are responsible for 60% to 70% of cases.

Optimal antimicrobial therapies for gram-negative bacillary meningitis have not been fully defined. The therapy of gram-negative meningitis is complex because of the variety of organisms that can infect the CNS. The treatment of meningitis due to *P. aeruginosa* remains a unique problem because antibiotics showing good antibacterial activity against *P. aeruginosa,* such as antipseudomonal penicillins and aminoglycosides, penetrate the CSF poorly. Furthermore, many isolates of *P. aeruginosa* are resistant to multiple, if not all, commonly used agents, and this trend in resistance is increasing. Initially, cases of *P. aeruginosa* meningitis should be treated with an extended-spectrum β-lactam such as ceftazidime or cefepime (A-II), or alternativly piperacillin ± tazobactam, or meropenem plus an aminoglycoside, usually tobramycin.[2] Since aminoglycosides penetrate the CSF poorly, their inclusion is predominantly to aid in the treatment of extracerebral infections. If multidrug-resistant *Pseudomonas* is suspected initially, intraventricular administration of aminoglycoside should be considered along with intravenous administration. Preservative-free forms of gentamicin and tobramycin are available and should be used for

direct administration into the CSF. Intraventricular aminoglycoside dosages should be adjusted to the estimated CSF volume (0.03 mg tobramycin or gentamicin per milliliter of CSF and 0.1 mg amikacin per milliliter of CSF every 24 hours). Since CSF flows unidirectionally with gravity, intraventricular aminoglycoside administration is more likely to produce therapeutic concentrations throughout the CSF than intrathecal administration. While intraventricular administration of aminoglycosides is considered for treatment of *P. aeruginosa* meningitis, this method produced higher mortality in a sample of infants treated for gram-negative bacillary meningitis.[22] Thus intraventricular administration of aminoglycosides to infants is not recommended routinely. Ventricular levels of aminoglycoside should be monitored every 2 or 3 days, just prior to the next intraventricular dose, and should approximate 2 to 10 mg/L. Interpretation of drug levels may be difficult because determinations often are contaminated with residual aminoglycoside from the preceding dose.

Multidrug-resistant *Pseudomonas* and *Acinetobacter* infections are of concern to clinicians because of the limited therapeutic options available for the treatment. This concern has led to the reemergence of the use of older antibiotics, such as colistin. Colistin can be used, both intravenously and intrathecally, in the treatment of multidrug-resistant *Pseudomonas* or *Acinetobacter* CNS infections.[57–59] Furthermore, there is synergistic activity with the combination of colistin and ceftazidime against multidrug-resistant *P. aeruginosa*.[60] The use of colistin should be reserved for only the most severe cases.

Other gram-negative organisms causing meningitis, excluding *P. aeruginosa* and *Acinetobacter* spp, most likely can be treated with a third or fourth-generation cephalosporin, such as cefotaxime, ceftriaxone, ceftazidime or cefepime. Ceftazidime, however, may not be the best choice of empirical antibiotic for situations where the offending organism is not known initially because CSF antibiotic concentrations greater than 10 times the minimal bactericidal concentration (MBC) may not be produced reliably for gram-positive organisms. In adults, daily doses of 8 to 12 g/day of third-generation cephalosporins (2 g twice a day of ceftriaxone) should produce CSF concentrations of 5 to 20 mg/L. Ceftriaxone is not recommended for use in the neonatal period because of the potential for the displacement of bilirubin from albumin-binding sites.[2] Cefotaxime should be used in place of ceftriaxone in this situation.

Trimethoprim-sulfamethoxazole is useful in the management of the Enterobacteriaceae family and also may be useful in the management of *L. monocytogenes*.[2,8] One advantage of trimethoprim-sulfamethoxazole is that its penetration into the CSF does not depend on meningeal inflammation. Trimethoprim-sulfamethoxazole is not, however, bactericidal. Trimethoprim-sulfamethoxazole produces CSF levels of 1.9 to 5.7 mg/L for the former and 20 to 63 mg/L for the latter when given parenterally in doses of 10 mg/kg per day (trimethoprim) and 50 mg/kg per day (sulfamethoxazole).

Fluoroquinolones have good penetration into the CSF and are effective in animal models of both gram-negative and gram-positive meningitis. However, there are limited data on the efficacy of fluoroquinolones in clinical practice. Ciprofloxacin is recommended as an alternative for the treatment of *E. coli* and other *Enterobacterianeae* as well as *Pseudomonas aeruginosa* (A-III). Cefepime and meropenem represent other therapeutic options for the treatment of gram-negative bacterial meningitis, as does aztreonam (A-III).[2,34]

CSF cultures may remain positive for several days or more with a regimen that eventually will be curative. Therapeutic efficacy can be monitored through bacterial colony counts every 2 or 3 days, which should decrease progressively over the period of therapy. Therapy for gram-negative meningitis should be continued for a minimum of 21 days from the start of treatment.[15]

Bacillus Anthracis

B. anthracis is a large, endospore-forming, aerobic, gram-positive bacteria capable of producing infection via the cutaneous, pulmonary, or GI routes. Cases of meningitis have been reported following both cutaneous and inhalational infection. Prior to the bioterrorism-related outbreak of 11 inhalational and 12 suspected or confirmed cases of cutaneous anthrax in 2001, only 18 sporadic cases had occurred in the United States in the 20th century, with the last occurrence in 1976.[61] However, since the terrorist attack on the United States on September 11, 2001, heightened awareness of biologic warfare agents, which include *B. anthracis*, has percolated throughout the United States.

The major neurologic complication of anthrax infection is fulminant, rapidly fatal hemorrhagic meningoencephalitis. The inhalational form of anthrax seems to be a potent inducer of neurologic symptoms, and death usually occurs within a week for those with neurologic complications.[61] Neurologic manifestations may be the initial symptoms leading to the diagnosis of anthrax. An index case of fatal inhalational anthrax from bioterrorism developed acute fever, emesis, disorientation, and confusion. A computed tomographic (CT) scan of the head showed no abnormalities, but spinal tap revealed cloudy CSF, low CSF glucose concentration, high CSF protein concentration, increased leukocytes in the CSF, and large gram-positive bacilli in chains. Shortly thereafter, the patient developed a generalized seizure and died on the third hospital day.[62]

Consistent findings in the CSF of anthrax meningitis cases include a low CSF glucose level, marked infiltration of WBCs into the CSF, and the presence of gram-positive bacilli in chains. High suspicion of anthrax meningitis is warranted in the additional presence of grossly visible blood or elevated red blood cell counts in the CSF with hemorrhagic changes on a CT scan. Recent molecular advances can aid in the rapid diagnosis of *B. anthracis* infections. Rapid PCR techniques, such as the Light Cycler (Roche Applied Science, Indianapolis, IN), can produce molecular confirmation for the presence of anthrax within 1 hour.[61] Extreme caution is warranted for diagnosis without the use of molecular techniques because *B. anthracis* can be confused easily with *B. cereus*, which is found commonly in soil and often considered a contaminant if identified.

B. anthracis typically is susceptible to penicillin, amoxicillin, erythromycin, doxycycline, ciprofloxacin, and chloramphenicol. The bioterrorism-related strain was susceptible to the fluoroquinolones, rifampin, tetracycline, vancomycin, imipenem, meropenem, chloramphenicol, clindamycin, and the aminoglycosides. However, the strain was resistant to third-generation cephalosporins and trimethoprim-sulfamethoxazole. Ciprofloxacin or doxycycline plus one or two of the aforementioned antibiotics is the currently recommended regimen for the treatment of inhalational anthrax, but doxycycline is not recommended for the treatment of anthrax meningitis owing to poor CNS penetration and recent in vitro resistance.[61]

Dexamethasone as an Adjunctive Treatment for Meningitis In addition to antibiotics, dexamethasone has become a commonly used therapy in the treatment of meningitis. Corticosteroids inhibit the production of TNF and IL-1, both potent proinflammatory cytokines. A series of clinical studies assessing the efficacy of corticosteroid therapy for the initial treatment of bacterial meningitis indicates conflicting results.[63–67] A fundamental problem with corticosteroid investigations to date is that the majority of patients in the trials had *H. influenzae* meningitis. While *H. influenzae* was the most commonly identified causative pathogen responsible for bacterial meningitis in the United States in 1986, the incidence of *H. influenzae* meningitis has decreased dramatically because of the introduction of polysaccharide con-

jugate vaccines. Additionally, the majority of studies examining dexamethasone use for pneumococcal meningitis were conducted before the widespread problem of penicillin-resistant pneumococcus had emerged, or in parts of the world where penicillin resistance is minimal. Whether or not steroids are beneficial in meningitis caused by penicillin-resistant *S. pneumoniae*, *N. meningitidis*, and group B streptococci is unclear at this time.

Significant improvement in markers of active infection, such as CSF levels of proinflammatory cytokines, as well as CSF protein, glucose, and lactate concentrations, have been shown after corticosteroid administration as adjunctive treatment.[14] Trials consistently detected a significantly lower incidence of neurologic sequelae commonly associated with bacterial meningitis with corticosteroid use. In trials that measured inflammatory mediators, lower levels of TNF, PAF, or IL-1 were detected in patients treated with dexamethasone.[63,64,67]

Most clinical trials on the use of adjunctive dexamethasone in bacterial meningitis have involved children. A retrospective analysis of pediatric patients with pneumococcal meningitis and one unblinded, noncontrolled trial suggested that adjunctive steroids may decrease the neurologic sequelae and mortality associated with *S. pneumoniae* meningitis.[63,68] A meta-analysis suggests that with the possible exception of hearing loss, dexamethasone does not protect against neurologic sequelae.[69] The protective effect of dexamethasone was observed to be strongest in those with meningitis due to *H. influenzae*.

10 The American Academy of Pediatrics suggests that dexamethasone be considered for infants and children 2 months of age or older with pneumococcal meningitis (C-II) and be given to those with *H. influenzae* meningitis.[55,70] The recommended intravenous dose is 0.15 mg/kg every 6 hours for 4 days. Alternatively, prospective, randomized, double-blind studies have found dexamethasone 0.15 mg/kg every 6 hours for 2 days or dexamethasone 0.4 mg/kg every 12 hours for 2 days to be equally effective and potentially less toxic.[67,71] Dexamethasone should be administered prior to or with the first antibiotic dose and not after antibiotics already have been started (A-I).[14] Additionally, serum hemoglobin and stool guaiac should be monitored for evidence of GI bleeding.[64,66,68,71] Dexamethasone should not be used in neonates or any infant younger than 6 weeks of age.[14,22] The use of dexamethasone interferes with the interpretation of clinical response to treatment. For example, corticosteroid use interferes with the resolution of fever. Thus all infants and children are recommended to undergo a repeat lumbar puncture after 24 to 48 hours of treatment to verify CSF sterilization.[14]

Data supporting the use of corticosteroids in adults with meningitis is scarce. A prospective, randomized, double-blind multicenter study evaluated the use of adjuvant therapy plus dexamethasone compared with adjuvant therapy plus placebo in adults with acute bacterial meningitis.[72] Early treatment with dexamethasone improved clinical outcome in adults with bacterial meningitis, reducing the risk of both unfavorable outcome and death. However, the study did not show a beneficial effect of dexamethasone on neurologic sequelae, including hearing loss. Furthermore, a meta-analysis of five trials involving 623 adults with actue bacterial meningitis described a significant reduction in mortality in patiens treated with steroids and antibiotics compared to those treated with antibiotics alone. There was not however a significant reduction in neurologic sequelae, but this could have been limited by the sample size considering two of the five trials did not investigate neurologic complications. The safety and adverse events were similar between those who received steroids and those who did not.[73]

If pneumococcal meningitis is suspected or proven, it is recommended that adults receive dexamethasone 0.15 mg/kg every 6 hours for 2 to 4 days with the first dose administered 10 to 20 minutes prior to first dose of antibiotics. Patient outcome is unlikely to improve if dexamethasone is given after first dose of antibiotic and should therefore be avoided (A-I). It is often difficult to ascertain the responsible pathogen on presentation therefore some clinicians recommend initiating dexamethasone in all adult patients presenting with meningitis (B-III).

Routine use of dexamethasone in meningitis is not without controversy. A potential concern is that adjunctive dexamethasone therapy might reduce the penetration of antibiotics into the CSF by inhibiting meningeal inflammation. In experimental models of meningitis, steroids decreased the CSF concentrations of ampicillin, rifampin, vancomycin, and gentamicin.[67,74] Ceftriaxone and vancomycin penetration into CSF was unaffected by concurrent dexamethasone administration in pediatric patients.[75,76]

CLINICAL CONTROVERSY

Some clinicians believe that dexamethasone should be initiated in all patients over the age of 2 months with bacterial meningitis and continued for the recommended 2 to 4 days regardless of bacterial etiology. Others, however, believe corticosteroids have limited proven benefit in the treatment of non-pneumococcal meningitis and recommend stopping dexamethasone if another bacterial pathogen is identified.

Mycobacterium Tuberculosis

M. tuberculosis is the primary cause of tuberculous meningitis. Tuberculous meningitis is associated with significant morbidity and mortality and is difficult to diagnose in a timely manner. The most life-threatening form of extrapulmonary tuberculosis is tuberculous meningitis.[77] The epidemiology of tuberculous meningitis as a cause of extrapulmonary tuberculosis has changed. Between the years 1997 and 1990, an average of 193 cases of tuberculous meningitis were reported to the CDC, representing 4.7% of extrapulmonary cases. The number of cases reported in 1990 was 284, or 6.2% of extrapulmonary cases. This change is most likely secondary to HIV/AIDS and rising rates among minority adults leading to increased tuberculosis in their children.[78] The incidence of tuberculosis in general has increased 15% since 1985, and the increase is more substantial in children than in adults.[77]

The most useful clue to diagnose tuberculous meningitis is the presence of inflammation of the CSF in an individual who is at epidemiologic risk for tuberculosis. Although up to 40% of patients may present with evidence of pulmonary involvement with hilar adenopathy, tuberculous meningitis still may exist in the absence of disease in the lung or extrapulmonary sites. The tuberculin skin test (purified protein derivative [PPD]) is also negative in 5% to 50% of cases.[79]

On initial examination, CSF usually contains from 100 to 1,000 WBCs/mm^3, which may be 75% to 80% polymorphonuclear cells. Over time, the pattern of WBCs in the CSF will shift to lymphocytes and monocytes (see Table 115–1). CSF glucose concentration may be normal initially but gradually decreases as the disease progresses.[79,80] Protein concentration within the CSF may be normal or elevated, with high protein levels shown to correlate with advanced disease.[79–81] CSF cultures often are positive for *M. tuberculosis* even if the patient is asymptomatic.

One potentially useful diagnostic sign unique to tuberculous meningitis is paralysis of the VI cranial nerve, which initially is unilateral and then progresses to bilateral.[30] Initial acid-fast bacilli (AFB) smears are approximately 37% sensitive and as high as 87% sensitive following subsequent smears. Sensitivity of the AFB smear

is enhanced by the examination of multiple CSF specimens collected on consecutive days. Cultures of CSF are positive in 45% to 90% of cases depending on the quantity of CSF used in the culture, pathogen density, and experience of the laboratory in culturing *M. tuberculosis*. Some clinicians will obtain fluid from the base of the brain or the ventricles in an attempt to increase the yield. Positive culture results may take up to 8 weeks, providing little help with the initial diagnosis.[79,80] Several systems employing rapid broth culture (Organon Teknika MB/BacT, Organon Teknika, Durham, NC; ESP system, Trek Diagnostic Systems, Inc., Westlake, OH; and Bactec 9000 TB series or Bactec 460, Becton Dickinson Diagnostic Instruments, Sparks, MD) have considerably shortened the time to detection and are able to detect organisms in less than 3 weeks.[18] Nucleic acid amplification products, such as Amplicor (Roche) and MTD (Genprobe), allow for the direct identification of *M. tuberculosis* within 48 hours and yield higher sensitivity than a smear.

Unfortunately, the incidence of multidrug-resistant strains of *M. tuberculosis* has increased, necessitating the use of at least three antitubercular agents to treat active pulmonary disease. The CDC recommends an initial regimen of four drugs for empirical treatment of *M. tuberculosis*.[82] This regimen consists of isoniazid, rifampin, pyrazinamide, and ethambutol 15 to 20 mg/kg per day (maximum 1.6 g/day) for the first 2 months, generally followed by isoniazid plus rifampin for the remaining duration of therapy. The recommended therapy for HIV-positive individuals is the same as for immunocompetent patients, although rifabutin may be considered in place of other rifamycins in an effort to minimize drug interactions with protease inhibitors and nonnucleoside reverse-transcriptase inhibitors. Therapy in HIV-negative and HIV-positive patients should be individualized based on susceptibility patterns and guidelines from the CDC and the American Thoracic Society, which are updated frequently and available on the Internet (*www.cdc.gov/nchstp/tb/pubs/mmwrhtml/maj_guide.htm*). Patients with *M. tuberculosis* meningitis should be treated for 9 months or longer with multiple-drug therapy, and patients with rifampin-resistant strains should receive 18 to 24 months of therapy.

Isoniazid, the mainstay in virtually any regimen to treat *M. tuberculosis,* penetrates the CSF with or without meningeal inflammation and achieves concentrations of more than 30 times the MIC of *M. tuberculosis* (MICs of 0.05–0.2 mg/L).[56,79,80] Rifampin's penetration of CSF approximates only 20% of serum concentrations in the presence of meningeal inflammation. *M. tuberculosis* typically is so exquisitely sensitive to rifampin, however, that the low penetration ratio is of little clinical significance.[79,80,83] However, the incidence of *M. tuberculosis* resistance to rifampin has increased, necessitating empirical multiple-antibiotic regimens.

Pyrazinamide is a small molecule that penetrates the CSF well in the presence or absence of meningeal inflammation. Streptomycin, an aminoglycoside, penetrates the CSF poorly, even in the presence of meningeal inflammation. The incidence of resistance to streptomycin is increasing, and this drug should not be recommended unless susceptibility is known. Ethambutol is a weak antitubercular agent that reaches the CSF in moderate concentrations. Ethambutol's use is also limited by a high incidence of dose-related optic neuritis. Ethionamide and cycloserine are two other agents that sometimes are used to treat tuberculous meningitis. These agents both penetrate the CSF well in the absence of meningeal inflammation.[79,80]

The usual dose of isoniazid in children is 10 to 15 mg/kg per day (maximum 300 mg/day), and adults usually receive 5 mg/kg per day or a daily dose of 300 mg.[82] Supplemental doses of pyridoxine hydrochloride (vitamin B_6) 50 mg/day are recommended to prevent the peripheral neuropathy associated with isoniazid administration.[79,80] Concurrent administration of rifampin is recommended at doses of 10 to 20 mg/kg per day (maximum 600 mg/day) for children and 600 mg/day for adults. The addition of pyrazinamide (children and adults 15–30 mg/kg per day; maximum in both 2 g/day) to the regimen of isoniazid and rifampin is recommended.[82] Duration of concomitant pyrazinamide therapy generally should be limited to 2 months to avoid hepatotoxicity.

The role of steroids in the management of tuberculous meningitis remains unclear. The administration of oral prednisone 60 to 80 mg/day or 0.2 mg/kg per day of intravenous dexamethasone for adults and prednisone 1 to 2 mg/kg per day for children, tapered over 4 to 8 weeks, has been used in clinical practice. Corticosteroids improve neurologic sequelae and survival in adults and decrease mortality, long-term neurologic complications, and permanent sequelae in children. Concerns regarding the use of steroids include a possible interference with CSF chemistry studies and decreased penetration of antitubercular agents because of a decrease in inflammation. Despite the controversy, the trend toward an improved outcome generally supports their use for tuberculous meningitis.[84,85]

Tuberculous meningitis has a mortality rate of 10% to 50% despite early diagnosis and treatment.[79,80,86] The level of patient consciousness at the start of therapy is the most useful prognostic indicator. Patients who are comatose at the beginning of therapy have a mortality rate of approximately 75%.[80] Other negative prognostic factors include old age, poor nutrition, evidence of miliary disease, high initial CSF protein concentrations, presence of hydrocephalus, and evidence of elevated ICP.[80] Bewteen 10% and 30% of patients surviving the disease have physical or mental sequelae, including deafness, vertigo, and short-term memory loss.[79,80]

Cryptococcus Neoformans

Cryptococcal meningitis is the most common form of fungal CNS infection in the United States and is a major cause of morbidity and mortality in immunosuppressed patients. In the United States, 85% of cases occur in HIV-infected patients. *C. neoformans* is a soil fungus acquired by inhalation of spores from the environment leading to pneumonia, which is usually asymptomatic. Most patients present initially with disseminated disease, especially meningoencephalitis. The incubation period in AIDS patients may be very short, as opposed to a relatively normal host, in whom it may be very long.

Symptoms of cryptococcal meningitis are insidious and may be present for varying periods, depending on the host involved, before the definitive diagnosis is made. Fever and a history of headaches are the most common symptoms, although altered mentation and evidence of focal neurologic deficits may be present. Examination of the CSF usually reveals small numbers of WBCs (<150/mm^3), which are primarily lymphocytes (see **Table 115–1**). Diagnosis is based on the presence of a positive CSF, blood, sputum, or urine culture for *C. neoformans*. The CSF cultures are positive in more than 90% of cases. Organisms may be seen by microscope when stained with india ink and are more likely to be seen in AIDS patients compared with other hosts. An additional rapid test helpful in diagnosis is latex agglutination, which detects the presence of cryptococcal antigens.[89] Latex agglutination is positive in more than 90% of culture-positive cases. A cryptococcal antigen test can be used to follow the prognosis of non-AIDS patients, but cryptococcal antigen titers do not correlate well with treatment efficacy in AIDS patients.[88] A cryptococcal antigen detection test needs to be considered in any patient presenting initially with meningitis. Risk factors predictive of a poor outcome include lethargy at presentation, high CSF cryptococcal antigen titer, and low CSF WBC count.[89]

Despite poor penetration into the CSF, amphotericin B has long been the drug of choice for the treatment of acute *C. neoformans* meningitis. Amphotericin B 0.5 to 1 mg/kg per day combined with flucytosine 100 mg/kg per day is more effective than amphotericin alone, with successful outcomes in 75% of non-AIDS patients and

50% in AIDS patients.[90] Unfortunately, in the AIDS population, flucytosine is often poorly tolerated, causing bone marrow suppression and GI distress. Amphotericin B alone, although less effective, has been used in AIDS patients with preexisting granulocytopenia.[90,91] Because of the high acute mortality rate of up to 40% and a relapse rate of 50% in AIDS patients receiving therapy, many new agents and regimens are being investigated in this population.[89] A small, noncomparative open study evaluating the safety and efficacy of liposomal amphotericin B (AmBisome) found the product to be well tolerated and moderately effective.[92] A second study found high-dose liposomal amphotericin B (4 mg/kg) to clear CSF cultures more rapidly relative to standard amphotericin B, although clinical efficacy was not significantly different.[93]

Azole therapy is the most studied alternative regimen for the treatment of *C. neoformans* meningitis in AIDS patients. Fluconazole at doses of 200 mg/day was compared with amphotericin B alone (0.4 mg/kg/day) with no significant difference in overall mortality between groups. However, patients receiving fluconazole had a higher 2-week mortality rate and time to CSF conversion.[94] High-dose fluconazole therapy (800 mg/day) was tried as salvage therapy in eight AIDS patients who failed previous antifungal therapy, but success was limited.[95] A randomized trial in Thailand compared amphotericin B (0.7mg/kg daily), amphotericin B plus flucytosine (100mg/kg daily), amphotericin B plus fluconazole (400mg daily) and triple therapy with amphotericin B, flucytosine and fluconazole daily for the treatment of HIV-associated cryptococcal meningitis. The addition of fluconazole to the standard therapy of amphotericin B plus flucytosine resulted in less fungicidal activity against *C. neoformans* than the current standard of amphotericin B plus flucytosine.[96] Itraconazole 200 mg orally twice daily was less effective than amphotericin B plus flucytosine in a small nonblinded study.[97] Voriconazole has demonstrated good in vitro activity against *C. neoformans*, however there are currently no comparative data to suggest an improvement over fluconazole.[98] Posaconazole has demonstrated clinical activity against cryptococcal and other fungal infections of the CNS in patients with refractory disease or otherwise intolerant to standard antifungal agents. Posaconazole appeared well tolerated at oral doses of 800 mg/day divided.[99] More data is needed to determine what role the new azole antifungal agents will play in future treatment of cryptococcal meningitis.

Patients with AIDS often require lifelong maintenance or suppressive therapy because of high relapse rates following acute therapy for *C. neoformans.* A large multicenter, controlled trial compared fluconazole (200 mg/day) and amphotericin B (1 mg/kg/wk) in the prevention of relapse.[100] Two percent of patients receiving fluconazole versus 18% of patients on amphotericin B relapsed. In addition, the amphotericin B group had significantly more frequent bacterial infections, bacteremias, and drug-related toxicity.[100] Fluconazole is superior to itraconazole in the prevention of relapse.[101] Current guidelines for patients with AIDS-associated cryptococcal meningitis recommend 2 weeks of therapy with a combination of amphotericin B 0.7 to 1 mg/kg/day and flucytosine 100 mg/kg/day. This is often referred to as the induction phase and is followed by 8 weeks of fluconazole 400 mg/day as part of the consolidation phase. Therapy should then be continued thereafter with fluconazole 200 mg/day until immune reconstitution takes place. Guidelines for the prevention of opportunistic infections in HIV-infected persons are updated frequently and can be found at *www.aidsinfo.nih.gov.*

Viral Encephalitis

The epidemiology of viral encephalitis in the United States has changed dramatically since the mid-1960s because of the introduction of large-scale polio and mumps immunization programs. In the United States, the incidence of mumps has decreased 98% between 1967 and 1985. Worldwide, mumps remains a causative agent of viral encephalitis in countries with low vaccination rates. Poliomyelitis, once a significant cause of encephalitis, is now confined to only a few less developed countries and likely soon will be eradicated as an infectious agent.

Nonpolio enteroviruses such as coxsackieviruses A and B, echoviruses, and enteroviruses 70 and 71 cause approximately 85% of all viral encephalitis cases.[102,103] The remaining 10% to 15% of viral encephalitis cases are caused by a variety of pathogens, such as arboviruses, adenoviruses, influenzae virus A and B, rotavirus, corona virus, cytomegalovirus, varicella-zoster, herpes simplex virus, Epstein-Barr virus, and lymphocytic choriomeningitis.[18,102] In the past, the St. Louis and LaCrosse viruses have been the most common cause of arbovirus encephalitis.[18] However, in 2002, the largest arboviral meningoencephalitis epidemic in the western hemisphere was caused by the West Nile Virus, accounting for 4,156 human cases of West Nile disease in 44 states and the District of Columbia.[104] To date, nearly 20,000 cases of West Nile disease and almost 800 deaths have been reported in the United States since surveillance began in 1999.[105]

Viral encephalitis is acquired primarily by hematogenous spread or, alternatively, by neuronal spread of the causative pathogen. After entry into the host, viral replication occurs, resulting in dissemination through the reticuloendothelial system or vasculature. Infection of the capillary endothelial cells and choroid plexus may provide a conduit for CNS infections. Viruses such as polio, herpes, and varicella-zoster virus also may gain access to the CNS by axonal retrograde transmission from peripheral nerve endings.[106] Once a virus gains access to the CNS, the course of infection depends on the virulence of the particular virus and the host immune response. Host response to aseptic CNS infections is mediated by a complex cascade of inflammatory cytokines in a manner similar to purulent meningitis. In contrast with purulent meningitis, host response to viral encephalitis is mediated primarily through cytotoxic T-lymphocytes. Although TNF is a prominent mediator in purulent bacterial meningitis, TNF concentrations are not increased in viral encephalitis, whereas increases in concentrations of IL-1 and interferon (INF)-α and -γ occur. TNF concentrations have been suggested as a diagnostic tool for differentiating between bacterial meningitis and viral encephalitis.[107] While cytokine assays are available for investigational use, they are not used routinely in the clinical diagnosis of viral encephalitis.

The clinical syndrome associated with viral encephalitis generally is independent of viral etiology and may vary depending on the patient's age. Common signs in adults include headache, mild fever (<40°C [<104°F]), nuchal rigidity, malaise, drowsiness, nausea, vomiting, and photophobia. Only fever and irritability may be evident in the infant, and meningitis must be ruled out as a cause of fever when no other localized findings are observed in a child. Duration of symptoms generally is 1 to 2 weeks, and specific manifestations outside the meninges also can occur depending on the viral etiology.

Laboratory examination of the CSF usually reveals a pleocytosis with 100 to 1,000 WBCs/mm^3, which are primarily lymphocytic; however, 20% to 75% of patients with viral encephalitis may have a predominance of polymorphonuclear cells on initial examination of the CSF, especially in enteroviral meningitis.[90] On repeat lumbar puncture, 90% of patients presenting initially with a predominance of neutrophils experience a shift to a predominance of mononuclear cells. Other laboratory findings include normal to mildly elevated protein concentrations and normal or mildly reduced glucose concentrations (see **Table 115–1**).[102]

Historically, pathogens responsible for viral encephalitis were not identified.[108] Poor laboratory recovery of viral pathogens and

limited treatment options for viral encephalitis made the need for specific identification of pathogens of questionable value. Advances in diagnostic laboratory techniques and the potential for decreased costs associated with longer duration of hospitalization for patients with unconfirmed viral encephalitis have led to a reevaluation of the need for confirmatory pathogen diagnosis.[109] When clinical signs warrant pathogen identification, appropriate laboratory diagnostic techniques, including PCR, should be undertaken. Molecular methods are preferred to conventional laboratory tests in the diagnosis of viral encephalitis owing to the ability to detect a specific virus in 30% to 70% of cases as compared with the 14% to 24% sensitivity of viral culture.[18]

Although there are numerous pathogenic causes of viral encephalitis, much of the clinical presentation, diagnosis, and treatment are similar. The most commonly isolated viral etiologies are described here.

Commonly, the incidence of enteroviral encephalitis peaks in late summer and continues into early fall. Enteroviruses are transmitted in the host via the fecal-oral route. Clinical presentation of enteroviral infection frequently is nonspecific and characterized by fever, nausea, vomiting, and malaise; however, GI symptoms may not be present. Following a prodrome of 1 to 2 days, headache, photophobia, and neck stiffness develop. Diagnosis can be confirmed by cell culture from the CSF, where the incidence of successful isolation has ranged from 40% to 80%.[107] In addition, enterovirus can be isolated from throat swabs (60%) and stool cultures (80%), but they are not necessarily diagnostic because the virus is shed in the stool for 1 to 2 weeks following infection.[108] Conversely, an enterovirus-specific reverse-transcriptase polymerase chain reaction (EV-PCR) test can provide prompt results within 24 hours with a sensitivity and a specificity of 100%.[110] Treatment for enteroviral encephalitis consists of supportive care, fluids, antipyretics, and analgesics. Generally, disease progression is self-limiting, and the patient recovers fully without long-term neurologic complications.

Both herpes simplex virus types 1 and 2 have been associated with infections of the CNS. Herpes simplex type 1 (HSV1) is associated with encephalitis in adults, whereas herpes simplex type 2 (HSV2) is associated predominantly with encephalitis in newborns.[103] An HSV infection of the CNS most likely is spread via retrograde movement from the dorsal root ganglion. Sexually active adults acquire herpes simplex meningitis during or after an attack of genital or rectal herpes. Although HSV2 frequently can be cultured from CSF, HSV1 cannot. As such, PCR may be more useful than culture in detecting infection with HSV; diagnosis is usually made by PCR, culture, or a 4-fold rise in complement-fixing antibody to the virus. Establishing the correct diagnosis as early as possible is paramount because mortality rates are between 50% and 85% without treatment, and unlike other viral encephalitides, specific and effective therapy is available. As a result, empirical therapy of suspected HSV encephalitis while laboratory results are pending is necessary. Additionally, a clinical decision to treat may need to be made regardless of test results.

Acyclovir is the drug of choice for herpes simplex encephalitis. In patients with normal renal function, acyclovir is usually administered as 10 mg/kg intravenously every 8 hours for 2 to 3 weeks.[103] Herpes virus resistance to acyclovir has been reported with increasing incidence, particularly from immunocompromised patients with prior or chronic exposures to acyclovir.[111] The alternative treatment for acyclovir-resistant herpes simplex virus is foscarnet.[103] The dose for patients with normal renal function is 40 mg/kg infused over 1 hour every 8 to 12 hours for 2 to 3 weeks. Ensuring adequate hydration is imperative. In addition, patients receiving foscarnet should be monitored for seizures related to alterations in plasma electrolyte levels.

Historically, the four most important arboviral pathogens in the United States were the St. Louis virus, the La Crosse virus, and the eastern and western equine viruses. However, the West Nile virus has been recognized as an emerging pathogen and has been implicated in an epidemic occurring in the United States since 1999. Transmission occurs through the bites of mosquitoes. Typically, an incubation period of 2 to 14 days precedes the onset of clinical symptoms. Infection of the brain tissue results in fever, headache, paralysis, and coma. While many patients have a benign presentation, symptomatic cases are associated with a higher degree of mortality. Mortality rates of 50% to 75% have been reported for eastern equine virus, whereas mortality rates for western equine and St. Louis viruses are 3% to 4% and 10% to 20%, respectively.[103,106] Treatment is supportive, including treatment for seizures and increased ICP, and in the majority of cases, the disease is self-limiting.[106]

Because of the recent epidemic in the United States, a separate discussion of the West Nile virus is warranted. Although West Nile virus is transmitted primarily by mosquitoes, transmission of the virus via blood products, organ transplantation, transplacental transfer, and breast milk has been documented.[104] Similar to the other arboviruses, the incubation period for West Nile virus ranges from 3 days to 2 weeks. West Nile virus infection is asymptomatic in most adults or causes a mild flulike syndrome characterized by fever, malaise, myalgia, and lymphadenopathy. Typically, less than 1% of patients develop neurologic disease, and approximately two-thirds have encephalitis, with the remainder having meningitis without encephalitis.[14] Many patients develop a maculopapular, erythematous rash, which is more common in children than in adults and is uncommon in other forms of viral encephalitis. The other neurologic manifestations include fever, nausea, vomiting, headache, altered mental status, movement disorders, and/or a syndrome much like poliomyelitis.[14,112,113] The primary risk factor for this manifestation seems to be advanced age. The poliomyelitis syndrome is characterized by an early prodromic phase of fevers and weakness followed by the sudden onset of flaccid paralysis. Among patients hospitalized with West Nile virus, the mortality rate is approximately 10% to 15%, whereas patients with encephalitis and weakness have a mortality rate of 30%. CSF examination of West Nile virus encephalitis typically shows pleocytosis and a slightly elevated CSF protein concentration.[14] Several diagnostic methods have been developed for West Nile virus, including a PCR assay and enzyme-linked immunosorbent assay (ELISA) tests. However, serologic tests (ELISA) can cross-react with other flaviviruses causing a false-positive result. Moreover, the IgM antibodies for West Nile virus can persist for up to 1 year, leading to confusion regarding whether the infection is an acute or previous infection.[14] Ribavirin has shown inhibitory effects on the West Nile virus in neural tissue cultures, but this has not been studied in controlled trials.

HIV encephalitis is the most common CNS complication associated with AIDS. Frequently, patients may complain of headache, photophobia, or stiff neck at the time of presumed seroconversion. As the disease progresses, however, neurologic symptoms are reported frequently secondary to other opportunistic infections. Diagnosis of viral encephalitis is difficult because mental status and neurologic examinations are not sensitive enough to detect early changes. Direct evidence of HIV encephalitis can be obtained through CSF culture, p24 antigen testing, or qualitative or quantitative PCR for HIV RNA. Diagnostic workup of other potential copathogens, such as herpes simplex virus (HSV), *Toxoplasma gondii*, *M. tuberculosis*, *Aspergillus* spp, and *Cryptococcus* also should be performed. Refer to Chapter 134 for a complete discussion of infectious complications in HIV-positive individuals.

EVALUATION OF THERAPEUTIC OUTCOMES

SIGNS AND SYMPTOMS

Because of the potential for rapid deterioration associated with meningitis, signs and symptoms of fever, headache, meningismus (e.g., nuchal rigidity, Brudzinski's or Kernig's sign), vital signs, and signs of cerebral dysfunction should be evaluated every 4 hours for the initial 3 days and then daily thereafter. The Glasgow Coma Scale should be used in severely ill patients. Trends in improvement and resolution rather than single evaluations in time are more important in monitoring the signs and symptoms of meningitis.

MICROBIOLOGIC FINDINGS

CSF and blood samples for Gram stain, cultures, and sensitivity testing should be taken prior to starting antibiotic therapy. If lumbar puncture is delayed, however, antibiotics should be started. Although the CSF cultures may be negative, antibiotic therapy rarely interferes with the protein and/or glucose concentrations in the CSF.[15] Furthermore, if the laboratory is made aware of the antibiotic therapy, steps can be taken to diminish the effects of the antibiotic during the detection process.[18] Gram stain results can be obtained immediately and can guide empirical antibiotic treatment. Identification of the organism can be made within 24 hours, and sensitivities should be available within 48 hours. Repeat cultures should be performed to help determine if sterilization is achieved. A second tube of blood should be taken to allow for latex agglutination tests of antigens to common meningeal pathogens (*H. influenzae*, *S. pneumoniae*, *N. meningitidis*, *E. coli*, and group B streptococcus) if the Gram stain has not been helpful.

CSF EXAMINATION

In bacterial meningitis, the CSF WBC count usually is greater than 1,000 cells/mm^3, the CSF protein concentration is elevated, and the CSF glucose concentration (hypoglycorachia) is often low (<50 mg/dL or 50%–60% of a simultaneous blood glucose value). Viral encephalitis, in contrast, results in relatively normal CSF protein and glucose levels and typically does not result in greater than 90% polymorphonuclear neutrophils (PMNs) in the CSF (see Table 115–1).

ABBREVIATIONS

AFB: acid-fast bacilli

AIDS: acquired immunodeficiency syndrome

BBB: blood–brain barrier

BCSFB: blood–cerebrospinal fluid barrier

CBF: cerebral blood flow

CDC: U.S. Centers for Disease Control and Prevention

CFU: colony forming unit

CNS: central nervous system

CSF: cerebrospinal fluid

CT: computed tomography

DIC: disseminated intravascular coagulation

EV-PCR: enterovirus-specific reverse-transcriptase polymerase chain reaction

FDA: U.S. Food and Drug Administration

GI: gastrointestinal

Hib: *H. influenzae* type b

HIV: human immunodeficiency virus

ICP: intracranial pressure

IL-1: interleukin 1

INF: interferon

LPS: lipopolysaccharide

MBC: minimum bactericidal concentration

MIC: minimum inhibitory concentration

NCCLS: National Committee for Clinical Laboratory Standards

PAF: platelet-activating factor

PCR: polymerase chain reaction

PGE_2: prostaglandin E_2

PPD: purified protein derivative

TNF: tumor necrosis factor

WBC: white blood cell

CHAPTER 116

Lower Respiratory Tract Infections

MARTHA G. BLACKFORD, MARK L. GLOVER, AND MICHAEL D. REED

KEY CONCEPTS

1. Respiratory infections remain the major cause of morbidity from acute illness in the United States and likely represent the most common reasons why patients seek medical attention.
2. The majority of pulmonary infections follow colonization of the upper respiratory tract with potential pathogens, whereas microbes less commonly gain access to the lungs via the blood from an extrapulmonary source or by inhalation of infected aerosol particles. The competency of a patient's immune status is an important factor influencing the susceptibility to infection, etiologic cause, and disease severity.
3. An appropriate treatment regimen for the patient with uncomplicated lower respiratory tract infection can be established by following the patient history, physical examination, chest radiograph, and properly collected sputum for culture and interpreted in light of current knowledge of the most common lung pathogens and their antibiotic susceptibility patterns within the community.
4. Acute bronchitis is caused most commonly by respiratory viruses and almost always is self-limiting. Therapy targets associated symptoms, such as lethargy, malaise, or fever (ibuprofen or acetaminophen), and fluids for rehydration. Routine use of antibiotics should be avoided and medication to suppress cough is rarely indicated.
5. Chronic bronchitis is caused by several interacting factors, including inhalation of noxious agents (most prominent are cigarette smoke and exposure to occupational dusts, fumes, and environmental pollution) and host factors including genetic factors and bacterial (and possibly viral) infections. The hallmark of this disease is a chronic cough, excessive sputum production, and expectoration with persistent presence of microorganisms in the patient's sputum.
6. Treatment of acute exacerbations of chronic bronchitis includes attempts to mobilize and enhance sputum expectoration (chest physiotherapy, humidification of inspired air), oxygen if needed, aerosolized bronchodilators (albuterol) in select patients with demonstrated benefit, and antibiotics.
7. Respiratory syncytial virus is the most common cause of acute bronchiolitis, an infection that mostly affects infants during their first year of life. In the well infant, bronchiolitis usually is a self-limiting viral illness, whereas in the child with underlying respiratory disease, cardiac disease, or both, the child may develop severe respiratory compromise (failure) necessitating in-hospital treatment, such as rehydration, oxygen, and, in select patients, bronchodilators, ribavirin aerosol, or both.
8. The most prominent pathogen causing community-acquired pneumonia in otherwise healthy adults is *S. pneumoniae*, whereas the most common pathogens causing hospital-acquired pneumonia (including nursing home residents) are *S. aureus* and gram-negative aerobic bacilli. Anaerobic bacteria are the most common etiologic agents in pneumonia that follows aspiration of gastric or oropharyngeal contents.
9. Treatment of community-acquired pneumonia may consist of humidified oxygen for hypoxemia, bronchodilators (albuterol) when bronchospasm is present, rehydration fluids, and chest physiotherapy for marked accumulation of retained respiratory secretions. Antibiotic regimens should be selected based on presumed causative pathogens and pulmonary distribution characteristics and should be adjusted to provide optimal activity against pathogens identified by culture (sputum or blood).
10. Treatment of nosocomial pneumonia requires aggressive therapy with careful consideration of the dominance and susceptibility patterns of the pathogens present within the institution. The epidemiology of these common pathogens should be evaluated on a regular basis in order to identify changing resistance patterns and subsequent alternation of treatment guidelines.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Respiratory tract infections remain the major cause of morbidity from acute illness in the United States and most likely represent the single most common reason patients seek medical attention. This chapter focuses on bacterial and viral infections involving the lower respiratory tract, which includes the tracheobronchial tree and lung parenchyma.

2 The respiratory tract has an elaborate system of host defenses, including humoral immunity, cellular immunity, and anatomic mechanisms.[1] When functioning properly, the host defenses of the respiratory tract are markedly effective in protecting against pathogen invasion and removing potentially infectious agents from the lungs. For the most part, infections in the lower respiratory tract occur only when these defense mechanisms are impaired, as in cases of dysgammaglobulinemia or compromised ciliary function, such as that caused by the chronic inflammation accompanying cigarette smoking. In addition, local defenses may be overwhelmed when a particularly virulent microorganism or excessive inoculum invades lung parenchyma. The majority of pulmonary infections follow

colonization of the upper respiratory tract with potential pathogens, which, after achieving sufficiently high concentrations, gain access to the lung via aspiration of oropharyngeal secretions. Less commonly, microbes enter the lung via the blood from an extrapulmonary source or by inhalation of infected aerosolized particles. The specific type of pulmonary infection caused by an invading microorganism is determined by a variety of host factors, including age, anatomic features of the airway, and specific characteristics of the infecting agent.

The most common infections involving the lower respiratory tract are bronchitis, bronchiolitis, and pneumonia. Lower respiratory tract infections in children and adults most commonly result from either viral or bacterial invasion of lung parenchyma. The diagnosis of viral infections rests primarily on the recognition of a characteristic constellation of clinical signs and symptoms. Because treatment is largely supportive, only occasionally does the diagnosis require laboratory confirmation; this is achieved through serologic tests or identification of the organism by culture or antigen detection in respiratory secretions.[2] Laboratory techniques using polymerase chain reaction (PCR) and genetic "fingerprinting" technology have emerged as a means to identify specific pathogens rapidly and accurately.[3]

In contrast, because bacterial pneumonia usually necessitates expedient, effective, and specific antibiotic therapy, its management depends, in large part, on an understanding of the risk factors for acquiring pneumonia, predominate pathogens within the community and, if necessary, isolation of the etiologic agent by culture from lung tissue or secretions.[4–7] The pharynx is colonized with many organisms that can cause pneumonia; therefore, culture of expectorated sputum can be misleading unless the specimen is examined to ensure that it has originated from the lower respiratory tract. The Gram stain provides the easiest method for distinguishing lower from upper respiratory tract secretions; moreover, through determination of the shape and color of the bacteria, the Gram stain frequently narrows the microbiologic differential diagnosis sufficiently to allow accurate initial therapy. Scanned under low-power microscopy, Gram-stained expectorated upper respiratory tract secretions contain many irregularly shaped epithelial cells with little evidence of inflammation and may not reflect the pathogen. In contrast, a lower-tract specimen from a patient with bacterial pneumonia usually contains multiple neutrophils per high-powered field and a single or predominant bacterial species. Culture of specimens confirmed to originate from the lower tract by Gram stain provides valuable diagnostic information for the majority of patients with bacterial pneumonia. In addition, pneumonia promotes the release of inflammatory mediators and acute phase proteins such as C-reactive protein, which is significantly elevated in serum in the presence of respiratory tract infections.[8]

3 An appropriate treatment regimen for the patient with an uncomplicated lower respiratory tract infection usually can be established by history, physical examination, chest radiograph, and properly collected sputum cultures interpreted in light of the most common lung pathogens and their antibiotic susceptibility patterns within the community.[2,4,5,9,10] More sophisticated or invasive diagnostic methods (e.g., computed tomography, bronchoscopy, and lung biopsy)[11,12] should be reserved for very ill patients who are unable to expectorate sputum or who are not responding to empirical therapy or for pulmonary infections occurring in immunocompromised patients.

BRONCHITIS

Bronchitis and bronchiolitis are inflammatory conditions of the large and small elements, respectively, of the tracheobronchial tree. The inflammatory process does not extend to the alveoli. Bronchitis frequently is classified as acute or chronic. Acute bronchitis occurs in individuals of all ages, whereas chronic bronchitis primarily affects adults. Bronchiolitis is a disease of infancy.

ACUTE BRONCHITIS

Epidemiology and Etiology

Acute bronchitis occurs most commonly during the winter months, following a pattern similar to those of other acute respiratory tract infections. Cold, damp climates and the presence of high concentrations of irritating substances (e.g., air pollution, cigarette smoke) may precipitate attacks.

4 Respiratory viruses are by far the most common infectious agents associated with acute bronchitis.[13] The common cold viruses (rhinovirus and coronavirus) and lower respiratory tract pathogens (influenza virus and adenovirus) account for the majority of cases. Wider use of reverse transcriptase PCR diagnostic evaluations has identified respiratory viral pathogens previously undescribed as etiologic agents in acute bronchitis and bronchiolitis including the human metapneumovirus and bocavirus.[14] In children, similar pathogens are observed, with the addition of the parainfluenza viruses. Although the true incidence remains to be defined, *M. pneumoniae* appears to be a frequent cause of acute bronchitis. Additionally, *C. pneumoniae* (also referred to as *Chlamydophila*)[15,16] and *B. pertussis*[17] (agent responsible for whooping cough) have been associated with acute respiratory tract infections. Although a variety of bacteria, including *S. pneumoniae, Streptococcus* species, *Staphylococcus* species, and *Haemophilus* species, may be isolated from throat or sputum culture, these organisms probably represent contamination by normal flora of the upper respiratory tract rather than true pathogens. Although a primary bacterial etiology for acute bronchitis appears rare, secondary bacterial infection may be involved.

Pathogenesis

4 Because acute bronchitis is primarily a self-limiting illness and rarely a cause of death, few data describing the pathology are available. In general, infection of the trachea and bronchi yields hyperemic and edematous mucous membranes with an increase in bronchial secretions. Destruction of respiratory epithelium can range from mild to extensive and may affect bronchial mucociliary function. In addition, the increase in desquamated epithelial cells and bronchial secretions, which can become thick and tenacious, further impairs mucociliary activity. The probability of permanent damage to the airways as a result of acute bronchitis remains unclear but appears very unlikely. However, epidemiologic evaluations support the belief that recurrent acute respiratory infections may be associated with increased airway hyperreactivity and possibly the pathogenesis of asthma or chronic obstructive pulmonary disease (COPD).

Clinical Presentation

Acute bronchitis usually begins as an upper respiratory infection with nonspecific complaints.[13,18] Cough is the hallmark of acute bronchitis and occurs early. The onset of cough may be insidious or abrupt, and the symptoms persist despite resolution of nasal or nasopharyngeal complaints; cough may persist for up to 3 or more weeks. Frequently, the cough initially is nonproductive but then progresses, yielding mucopurulent sputum. In older children and adults, the sputum is raised and expectorated; in the young child, sputum often is swallowed and can result in gagging and vomiting. Substantial discomfort may result from the coughing. Dyspnea, cyanosis, or signs of airway obstruction are observed rarely unless the patient has underlying pulmonary disease, such as emphysema

or COPD. Fever, when present, rarely exceeds 39°C (102.2°F) and appears most commonly with adenovirus, influenza virus, and *M. pneumoniae* infections. The diagnosis typically is made on the basis of a characteristic history and physical examination. Bacterial cultures of expectorated sputum generally are of limited use because of the inability to avoid normal nasopharyngeal flora by the sampling technique. In routine cases, viral cultures are unnecessary and frequently unavailable. Viral antigen detection tests, developed to identify respiratory viral antigens from nasal secretions rapidly, can be obtained in many hospital laboratories and in some practice settings when a specific diagnosis is necessary for clinical or epidemiologic reasons. Cultures, serologic or PCR diagnosis of *M. pneumoniae,* and culture direct fluorescent antibody detection or PCR for *B. pertussis* should be obtained in prolonged or severe cases when epidemiologic considerations would suggest their involvement.

TREATMENT

Acute Bronchitis

DESIRED OUTCOME

In the absence of a complicating bacterial superinfection, acute bronchitis almost always is self-limiting. The goals of therapy are to provide comfort to the patient and, in the unusually severe case, to treat associated dehydration and respiratory compromise.[13]

GENERAL APPROACH TO TREATMENT

4 Treatment of acute bronchitis is symptomatic and supportive in nature. Reassurance and antipyretics frequently are all that are needed. Bed rest for comfort may be instituted as desired. Patients should be encouraged to drink fluids to prevent dehydration and possibly to decrease the viscosity of respiratory secretions. Mist therapy (use of a vaporizer) may promote the thinning and loosening of respiratory secretions.

PHARMACOLOGIC THERAPY

Mild analgesic–antipyretic therapy often is helpful in relieving the associated lethargy, malaise, and fever. Aspirin or acetaminophen (650 mg in adults or 10 to 15 mg/kg per dose in children; maximum daily pediatric dose 60 mg/kg; maximum daily adult dose 4 g) or ibuprofen (200 to 800 mg in adults or 10 mg/kg per dose in children; maximum daily pediatric dose 40 mg/kg; maximum daily adult dose 3.2 g) should be administered every 4 to 6 hours. In children, aspirin should be avoided and acetaminophen used as the preferred agent because of the possible association between aspirin use and the development of Reye syndrome.[19]

Use of ibuprofen as an antipyretic has increased. The drug's antipyretic efficacy appears identical to that of aspirin or acetaminophen, although its duration of antipyretic effect may be slightly longer (e.g., 3 to 4 hours for aspirin and acetaminophen versus 5 to 6 hours for ibuprofen). Caution should be exercised in the administration of ibuprofen for patients younger than 3 months, elderly patients, and individuals with poor renal function. Aspirin and ibuprofen inhibit prostaglandin synthesis and may adversely influence renal function in these predisposed patient populations.

Patients may present with mild to moderate wheezing. In otherwise healthy patients, no meaningful benefits have been described with the use of oral or aerosolized β_2-receptor agonists and/or oral or aerosolized corticosteroids. A Cochrane Review showed limited benefit of β_2-receptor agonists even for patients with airflow obstruction. Nevertheless and despite no data, some clinicians may initiate a brief trial (e.g., ~5 to 7 days) of oral or inhaled corticosteroid for patients with persistent (>14 to 20 days), troublesome cough. Despite several studies, none support the use of mucolytic agents.

Patients suffering from acute bronchitis frequently medicate themselves with nonprescription cough and cold remedies containing various combinations of antihistamines, sympathomimetics, and antitussives despite the lack of definitive evidence supporting their effectiveness. In fact, the tendency of these agents to dehydrate bronchial secretions could aggravate and prolong the recovery process. Although not recommended for routine use, persistent, mild cough, which may be bothersome, can be treated with dextromethorphan; more severe coughs may require intermittent codeine or other similar agents.[13,18] In severe cases, the cough may be persistent enough to disrupt sleep, and use of a mild sedative–hypnotic, concomitantly with a cough suppressant (e.g. codeine), may be desirable. However, antitussives should be used cautiously when the cough is productive. The primary or supplemental use of expectorants is questionable because their clinical effectiveness has not been well established.

Routine use of antibiotics for treatment of acute bronchitis should be discouraged.[13] In previously healthy patients who exhibit persistent fever or respiratory symptoms for more than 4 to 6 days or for predisposed patients (e.g., elderly, immunocompromised), the possibility of a concurrent bacterial infection should be suspected. When possible, antibiotic therapy should be directed toward anticipated respiratory pathogen(s) (i.e., *S. pneumoniae). M. pneumoniae,* if suspected by history or if confirmed by culture serology or PCR, can be treated with azithromycin. Alternatively and empirically, a fluoroquinolone antibiotic with activity against these suspected pathogens (e.g., levofloxacin) can be used. During known epidemics involving the influenza A virus, amantadine or rimantadine may be effective in minimizing associated symptoms if administered early in the course of the disease though treatment with adamantanes is no longer CDC recommended due to increasing influenza resistance to these two agents.[20] The neuraminidase inhibitors (e.g., zanamivir and oseltamivir) are active against both influenza A and B viral infections and may reduce the severity and duration of the influenza episode if administered promptly during the onset of the viral infection and are the preferred treatment (see Chap. 118).[21,22] Unfortunately, the incidence of influenzae virus resistance to available antiviral drugs is increasing.[20,23]

CHRONIC BRONCHITIS

Epidemiology and Etiology

Chronic bronchitis, a component of the COPD is a clinical diagnosis for a nonspecific disease that primarily affects adults. An in-depth presentation of the spectrum and management of the COPDs is in Chap. 34. This section will focus solely on chronic bronchitis, a disease that affects most patients with COPD. In developed countries the prevalence of chronic bronchitis is nearly equal in men and woman and possibly more common in whites.[24,25]

5 Chronic bronchitis is defined clinically as the presence of a chronic cough productive of sputum lasting more than 3 consecutive months of the year for 2 consecutive years without an underlying etiology of bronchiectasis or tuberculosis. The disease is a result of several contributing factors; the most prominent include cigarette smoking, exposure to occupational dusts, fumes, and environmental pollution; and host factors [e.g., genetic factors and bacterial (and possibly viral) infections]. The contribution of each of these factors and of others (either alone or in combination) to chronic bronchitis is unknown. Cigarette smoke is a well-known

airway irritant and is believed to be the predominant factor in the etiology of chronic bronchitis. Although previously assumed the most common etiologic cause of chronic bronchitis, more strict prohibition of public smoking and the resultant decrease in chronic tobacco smokers, particularly in developed countries, underscores the importance of other factors as causes of this chronic disease. Additional airway irritants including occupational dust, chemicals, or air pollution, either alone or more probably in combination, are also responsible for the pathogenesis of chronic bronchitis. Furthermore, it appears from candidate gene association studies that a genetic basis for some COPD phenotypes will be identified in the near future.[25] Lastly, the influence of recurrent respiratory tract infections during childhood or young adult life on the later development of chronic bronchitis remains obscure, but recurrent respiratory infections may predispose individuals to the development of chronic bronchitis.[26] Whether these recurrent respiratory tract infections are a result of unrecognized anatomic abnormalities of the airways or impaired pulmonary defense mechanisms is unclear.

Chronic bronchitis is a disease of the bronchi and as noted above is manifested by cough and excessive sputum expectoration that occurs on most days of the week for a minimum of 3 consecutive months per year for at least 2 consecutive years that is unrelated to other pulmonary or cardiac disease. Numerous consensus statements and published authoritative guidelines define chronic bronchitis and emphysema as the two main components of COPD/chronic obstructive lung disease (COLD).[18,24,27] The Global Initiative for Chronic Obstruction Lung Disease (GOLD)[24] guidelines document does not distinguish these two diagnoses (e.g., emphysema or chronic bronchitis) in the definition of COPD, but it does define COPD as a disease characterized by airflow obstruction that is not fully reversible and progressive.[28] The GOLD guidelines provide a COPD classification scoring system according to severity that can be very helpful in staging patients for intensity of therapy and prognosis.[24] Unfortunately, differences in definitions between authoritative organizations[18,24,27] may cause confusion in the assignment of patients in clinical trials and thus to assessment and applications of study results to clinical care.

Pathogenesis

Chronic inhalation of an irritating noxious substance compromises the normal secretory and mucociliary function of bronchial mucosa. Bronchial biopsy specimens in bronchitic patients underscore the importance of proinflammatory cytokines [e.g., interleukins 1β, 6, and 8, transforming growth factor-β, leukotriene B4 and tumor necrosis factor-α] in the pathogenesis and propagation of the observed inflammatory changes. In chronic bronchitis, the bronchial wall is thickened, and the number of mucus-secreting goblet cells on the surface epithelium of both larger and smaller bronchi is increased markedly. In contrast, goblet cells generally are absent from the smaller bronchi of normal individuals. In addition to the increased number of goblet cells, hypertrophy of the mucous glands and dilation of the mucous gland ducts are observed. As a result of these changes, chronic bronchitics have substantially more mucus in their peripheral airways, further impairing normal lung defenses. This increased quantity of tenacious secretions within the bronchial tree frequently causes mucous plugging of the smaller airways. Accompanying these changes are squamous cell metaplasia of the surface epithelium, edema, and increased vascularity of the basement membrane of larger airways and variable chronic inflammatory cell infiltration. In addition, the amounts of several proteases derived from inflammatory cells are increased and due to COPD-induced defective antiproteases leads to continued destruction of connective tissue. Continued progression of this pathology can result in residual scarring of small bronchi and peribronchial fibrosis augmenting airway obstruction and weakening of bronchial walls.

Clinical Presentation

5 The hallmark of chronic bronchitis is a cough that may range from a mild to a severe, incessant coughing productive of purulent sputum. Coughing may be precipitated by multiple stimuli, including simple, normal conversation. Expectoration of the largest quantity of sputum usually occurs on arising in the morning, although many patients expectorate sputum throughout the day. The expectorated sputum usually is tenacious and can vary in color from white to yellow-green. Patients with chronic bronchitis often expectorate as much as 100 mL/day more than normal. As a result, many patients complain of a frequent bad taste in their mouth and of halitosis.

The diagnosis of chronic bronchitis is based primarily on clinical assessment and history. Any patient who reports coughing sputum on most days for at least 3 consecutive months each year for 2 consecutive years presumptively has chronic bronchitis.[28] The diagnosis of chronic bronchitis is made only when the possibilities of bronchiectasis, cardiac failure, cystic fibrosis, and lung carcinoma have been effectively excluded. In an attempt to be more specific in the diagnosis, some investigators have added the criteria of lost wages for 3 or more weeks. In addition, many clinicians attempt to subdivide their patients based on severity of disease to guide therapeutic interventions. A useful diagnostic/clinical severity-based classification system is often used to categorize patients to assist in defining an acute therapeutic strategy. The classification system used most often utilizes three descriptive categories: I. *Simple chronic bronchitis* best describes patients with no major risk factors and sputum flora reflects the common associated pathogens where the patient usually responds well to first-line oral antibiotic therapy; II. *Complicated chronic bronchitis* are those patients with what would be considered a "simple chronic bronchitis" exacerbation, but the patients have two or more disease-associated risk factors such as FEV_1 <50% predicted, age >64 years, >4 exacerbations per year, home oxygen use, underlying cardiac disease, use of immunosuppressants, or use of antibiotics for an exacerbation within the past 3 months. These group II patients may also harbor drug-resistant pathogens; III. *Severe complicated chronic bronchitis* are those patients with group II symptoms but clinically are much worse, for example, FEV_1 <35% predicted, >4 acute exacerbations per year, increased risk for infection with *P. aeruginosa* and presence of pathogens that are multidrug resistant (MDR). These later patients often require hospitalization and aggressive parenteral antibiotics including combination therapy. A clinical algorithm for the diagnosis and treatment of chronic bronchitic patients with an acute exacerbation incorporating the principles of the clinical classification system is shown in Figure 116–1. The importance of accurate classification for grouping patients of similar disease involvement cannot be overemphasized with respect to assessing publications outlining treatment strategies for these patients.[29] Although gross, these classifications attempt to capture specific subphenotypes of chronic bronchitis patients. It is hoped that within the next 2 to 4 years, pharmacogenomic advances will provide a more sophisticated tool for defining specific phenotypes linked to specific, optimal therapies.[30] The typical clinical presentation of chronic bronchitis is listed in Table 116–1. Comparison of the trends in changes in patient physical activity, symptoms and clinical/physical findings from the patient's "routine" is extremely helpful in determining the presence and severity of an acute exacerbation. In general, a good clinical relationship exists between the purulence of the sputum and the bacterial load (>90% of cases) and for sputum color, for example,

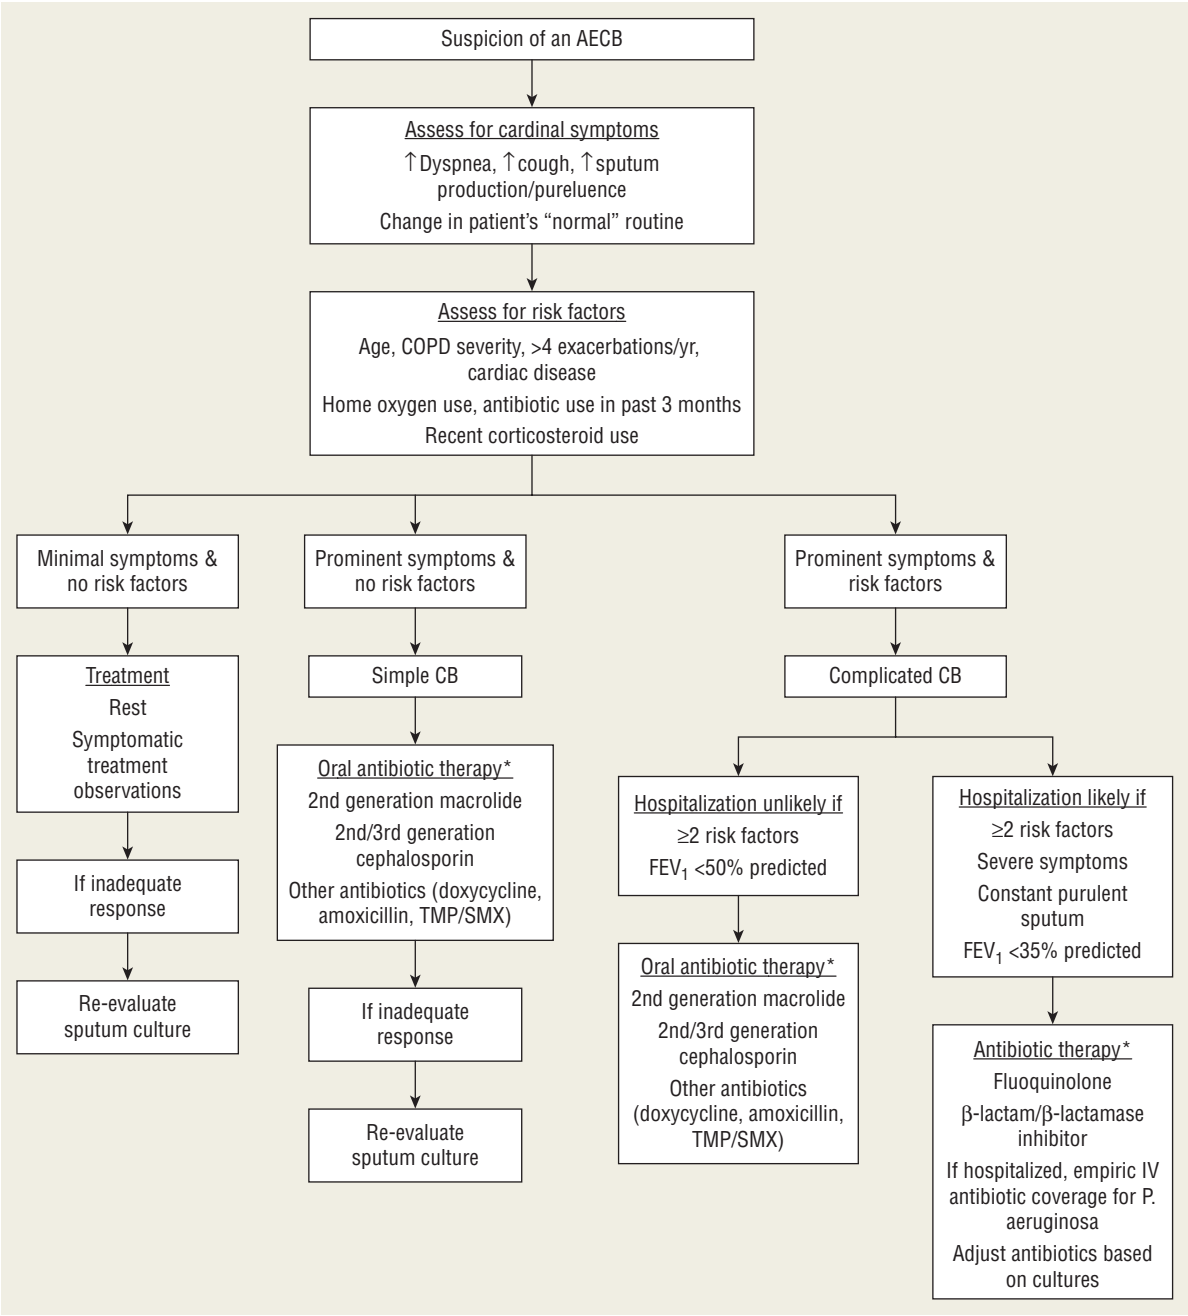

FIGURE 116-1. Clinical algorithm for the diagnosis and treatment of chronic bronchitic patients with an acute exacerbation incorporating the principles of the clinical classification system (AECB, acute exacerbation of chronic bronchitis; COPD, chronic obstructive pulmonary disease; CB, chronic bronchitis; TMP/SMX, trimethoprim/sulfamethoxazole). *See Table 116–4 for commonly used antibiotics and doses. *(Adapted from reference 36.)*

the greener the color the greater the amount of leukocyte myeloperoxidase (indicating that more inflammatory cells are present).

In more advanced stages of chronic bronchitis, physical findings associated with cor pulmonale, including cardiac enlargement, hepatomegaly, and edema of the lower extremities, are observed. In general, chronic bronchitics tend to maintain at least normal body weight and commonly are obese. Radiographic studies are of limited value in either the diagnosis or follow-up of a patient. The microscopic and laboratory assessments of sputum are considered important components in the overall evaluation of patients with chronic bronchitis. A fresh sputum specimen obtained as an early-morning sample is preferred. Comparison of the cellular constituents of chronic bronchitic sputum with those of normal sputum can provide insight into the degree of activity of the disease processes. An increased number of polymorphonuclear granulocytes often suggests continual bronchial irritation, whereas an increased number of eosinophils suggests an allergic component that should be further investigated. Gram staining of the sputum often reveals a mixture of both gram-positive and gram-negative bacteria, reflecting normal oropharyngeal flora and chronic tracheal colonization (in order of frequency) by nontypeable *H. influenzae, S. pneumoniae,* and *M. catarrhalis.* Table 116–2 lists the most common bacterial isolates identified from sputum culture for patients experiencing an acute exacerbation of chronic bronchitis. For patients with more severe airflow disease [e.g., forced expiratory volume in the first second of expiration (FEV_1) <40%], enteric gram-negative bacilli, *E. coli, Klebsiella* species, *Enterobacter* species, and *P. aeruginosa* may be significant pathogens during acute exacerbations.[31]

TABLE 116-1 Clinical Presentation of Chronic Bronchitis

Signs and symptoms
Excessive sputum expectoration
Cyanosis (advanced disease)
Obesity
Physical examination
Chest auscultation usually reveals inspiratory and expiratory rales, rhonchi, and mild wheezing with an expiratory phase that is frequently prolonged; hyperresonance on percussion with obliteration of the area of cardiac dullness
Normal vesicular breathing sounds are diminished
Clubbing of digits (advanced disease)
Chest radiograph
Increase in anteroposterior diameter of the thoracic cage (observed as a barrel chest)
Depressed diaphragm with limited mobility
Laboratory tests
Erythrocytosis (advanced disease)
Pulmonary function tests
Decreased vital capacity
Prolonged expiratory flow

TABLE 116-2 Common Bacterial Pathogens Isolated from Sputum of Patients with Acute Exacerbation of Chronic Bronchitis

Pathogen	Percent of Cultures
H. influenzae[a,b]	45
M. catarrhalis[a]	30
S. pneumoniae[c]	20
E.coli, Enterobacter species, *Klebsiella* species, *P. aeruginosa*	5

[a]Often β-lactamase positive.
[b]Vast majority are nontypeable strains.
[c]As many as 25% of strains may have intermediate or high resistance to penicillin.

TREATMENT

Chronic Bronchitis

DESIRED OUTCOME

The goals of therapy for chronic bronchitis are twofold: to reduce the severity of chronic symptoms and to ameliorate acute exacerbations and achieve prolonged infection-free intervals.

GENERAL APPROACH TO TREATMENT

The approach to treatment of chronic bronchitis is multifactorial. First and foremost, attempts must be made to reduce the patient's exposure to known bronchial irritants (e.g., smoking, workplace pollution). A complete occupational and environmental history for determination of exposure to noxious, irritating gases, as well as preference toward cigarette smoking, must be assessed. Often easier discussed than accomplished, honest, yet reasonable attempts should be made with the patient to reduce or eliminate the number of cigarettes smoked daily and to reduce exposure to secondhand smoke. In an organized, coordinated, smoking cessation program, including counseling and hypnotherapy, the adjunctive use of nicotine substitutes (e.g., nicotine gum or patch) or other pharmacotherapy (e.g. bupropion) may promote the reduction or complete withdrawal from cigarette smoking. Often just as difficult is modification of exposure to irritating substances within the home and workplace.

6 Measures to provide pulmonary toilet can be instituted. During acute pulmonary exacerbations of the disease, the patient's ability to mobilize and expectorate sputum may be reduced dramatically. In these instances, attempts at postural drainage techniques, with instruction, active participation, or both from a respiratory therapist, may assist in promoting clearance of pulmonary secretions. In addition, humidification of inspired air may promote the hydration (liquefaction) of tenacious secretions, allowing for removal that is more productive. Use of mucolytic aerosols, such as *N*-acetylcysteine and DNAse, is of questionable therapeutic value, particularly considering their propensity to induce bronchospasm (*N*-acetylcysteine) and their excessive cost. A Cochrane metaanalysis of mucolytic therapy in subjects with chronic bronchitis or COPD found that treatment with mucolytics was associated with a small reduction in acute exacerbations and a reduction in total number of days of disability. The clinical benefit may be greater for chronic bronchitics/COPD patients who have frequent or prolonged exacerbations or those who are repeatedly admitted to hospitals with acute exacerbations. Mucolytics may have the greatest benefit for patients with moderate or severe COPD who are not receiving inhaled corticosteroids.[32] Although limited data are available, chronic use of oral or aerosolized bronchodilators may be of benefit by increasing mucociliary and cough clearance. For patients with moderate to severe COPD, twice-daily inhaled salmeterol/fluticasone propionate 50:250 or 50:500 mcg for 24 to 52 weeks improves FEV_1 significantly more than does salmeterol or fluticasone monotherapy and results in clinically significant improvements in health-related quality of life.[33] Furthermore, patients may benefit from inhaled corticosteroids; patients with severe disease (FEV_1 <50%) with a history of frequent exacerbations should receive chronic inhaled corticosteroid therapy. Use of systemic corticosteroid therapy (oral or IV) for patients with an acute exacerbation significantly reduces treatment failures and the need for additional medical treatment.[34] Finally, in the face of an acute exacerbation, a trial of antibiotics directed against the most likely underlying pathogens should be initiated.

PHARMACOLOGIC THERAPY

For patients who consistently demonstrate clinical limitation in airflow, a therapeutic challenge of β_2-agonist bronchodilators (e.g., as albuterol aerosol) should be considered. Pulmonary function tests should be performed before and after β_2-agonist aerosol administration for more objective determination of a patient's propensity to benefit from supplemental aerosol therapy. Sufficient published experience supports the use of inhalation therapy with a β_2-agonist for patients with chronic bronchitis (COPD) to improve pulmonary function and exercise tolerance and to reduce the sense of breathlessness.[28] Regular use of a long-acting β-receptor agonist aerosol (e.g., salmeterol, formoterol) in responsive patients may be more effective and probably more convenient than short-acting β_2-receptor agonists. The aerosol route for β_2-receptor agonist and/or corticosteroid administration is favored over systemic formulations for improved patient acceptance, compliance and to minimize the number and magnitude of associated adverse effects.[24] Chronic inhalation of the salmeterol/fluticasone combination has been associated with improved pulmonary function and quality of life.

Published experience with inhaled anticholinergic drugs, including ipratropium and tiotropium, is limited. In stable patients, long-term inhalation of ipratropium has been associated with a decreased frequency of cough, less severe coughing, and a decrease in the volume of expectorated sputum. Once-daily tiotropium inhalation was associated with significant bronchodilation and dyspnea relief compared with placebo but had no significant effect on the incidence or severity of cough.[24,28] Although chronic theophylline

administration has been used extensively in the past, this therapy is used with decreasing frequency in favor of aerosolized β_2-receptor agonists. A salmeterol/fluticasone combination markedly reduced the number of chronic bronchitis-associated emergency room visits and hospitalizations compared to an ipratropium-based regimen.[35]

Use of antimicrobials for treatment of chronic bronchitis has been controversial but is becoming more accepted. Numerous comparative evaluations, including placebo-controlled studies of antibiotic administration with acute and chronic treatment of chronic bronchitics, have suggested definite clinical benefit, whereas other similar studies have not.[24,27,29,31,36] The antibiotics selected most frequently possess variable in vitro activity against the common sputum isolates *H. influenzae, S. pneumoniae, M. catarrhalis*, and *M. pneumoniae.* In general, conflicting published results appear independent of the antibiotic used or the regimen compared. The wide disparity that exists in the results from these studies, combined with the difficulties in recognition and lack of standardized diagnostic criteria for acute exacerbations of chronic bronchitis, serves as the basis for the enormous controversy surrounding the use of antibiotics in this condition.[37] A review of 14 double-blinded randomized clinical trials compared fluoroquinolones with more standard antibiotic regimens (e.g., macrolides, azalides, oral cephalosporins, and the combination drug amoxicillin/clavulanate).[31] As expected, no significant differences were observed between treatment arms. However, in a small subset of studies (n = 4), the sputum culture became negative in a significantly higher number of fluoroquinolone-treated patients. Other studies showed an increase in the interval between acute exacerbations for patients who received fluoroquinolone therapy. An additional advantage of fluoroquinolone therapy is the short course (e.g., 5 days) and once-daily dosing compared to other antibiotic regimens. A useful paradigm for the assessment and treatment of acute exacerbations of chronic bronchitis and antibiotic decision making is shown in Figure 116–1. Furthermore, many clinicians will use the so-called Anthonisen criteria to determine if antibiotic therapy is indicated. The Anthonisen criteria are as follows:[38] If a patient exhibits two of the following three criteria during an acute exacerbation of chronic bronchitis, the patient will most likely benefit from antibiotic therapy and thus, should receive a treatment course: (1) increase in shortness of breath; (2) increase in sputum volume; (3) production of purulent sputum. There are greater healthcare costs for patients who are noncompliant with their antibiotic regimen for their acute exacerbation of chronic bronchitis.[39]

The increasing resistance of the common bacterial pathogens to first-line agents further complicates antibiotic selection. As many as 30% to 40% of *H. influenzae* and 95% to 100% of *M. catarrhalis* isolates produce β-lactamases. Moreover, up to 40% of *S. pneumoniae* isolates demonstrate resistance to penicillin [minimum inhibitory concentration (MIC) = 0.1 to 2 mg/L], with approximately 20% of isolates being highly resistant (MIC>2 mg/L). Concern regarding *S. pneumoniae* resistance is increasing, now ≥30% for macrolides. Despite these changes in bacterial susceptibility, the current recommendation is to initiate therapy with first-line agents in less severely affected patients (see Fig. 116–1). Trimethoprim/sulfamethoxazole has been extremely useful for patients with less severe disease.[40] However, the public campaign in the United Kingdom by the Committee of Safety of Medicines to discourage the use of trimethoprim/sulfamethoxazole based on rare but possibly life-threatening cases of Stevens-Johnson syndrome has markedly reduced the use of this agent worldwide. For patients with more moderate to severe disease, many clinicians will begin antibiotic therapy with the second line agents, amoxicillin/clavulanate, a macrolide (such as azithromycin or clarithromycin) (they are being used less frequently) and more frequently with a fluoroquinolone, such as levofloxacin (see Fig. 116–1).[24,31,36,41]

TABLE 116-3 Oral Antibiotics Commonly Used for the Treatment of Acute Respiratory Exacerbations in Chronic Bronchitis

Antibiotic	Usual Adult Dose (mg)	Dose Schedule (Doses/Day)
Preferred drugs		
Ampicillin	250–500	4
Amoxicillin	500–875	3–2
Amoxicillin/clavulanate	500–875	3–2
Ciprofloxacin	500–750	2
Levofloxacin	500–750	1
Moxifloxacin	400	1
Doxycycline	100	2
Minocycline	100	2
Tetracycline HCl	500	4
Trimethoprim/sulfamethoxazole[a]	1 DS	2
Supplemental drugs		
Azithromycin	250–500	1
Erythromycin	500	4
Clarithromycin	250–500	2
Cephalexin	500	4

[a]DS, double-strength tablet (160-mg trimethoprim/800-mg sulfamethoxazole).

Regardless of the antibiotic selected, careful attention to predetermined outcome measures should be monitored closely for each patient to determine the success or failure of the therapeutic intervention. Oral antibiotics with broader antibacterial spectra (e.g., amoxicillin/clavulanate, fluoroquinolones, or azalides) that possess potent in vitro activity against sputum isolates are increasingly becoming first-line antibiotics as initial therapy for treatment of acute exacerbations of chronic bronchitis.[24,31,35,36,40]

An important clinical outcome variable directing drug selection and criteria for beginning antibiotics in individual patients is the infection-free period when chronic bronchitics are off antibiotics. The actual length of the infection-free time period and the change in the number of physician office visits and hospital admissions with a particular antibiotic regimen are extremely important to identify, whenever possible, for each patient. The antibiotic regimen that results in the longest infection-free period defines the "regimen of choice" for specific patients for future acute exacerbations of their disease.

Antibiotics should be selected that are effective against responsible pathogens, demonstrate the least risk of drug interactions, and can be administered in a manner that promotes compliance. Antibiotics commonly used for treatment of these patients and their respective adult starting doses are listed in Table 116–3. Doses of antibiotics should be adjusted as needed to the desired clinical effect and the lowest incidence of acceptable side effects. A frequently used clinical strategy to enhance the duration of symptom-free periods incorporates higher-dose antibiotic regimens using the upper limit of the recommended daily antibiotic dose for a period of 5 to 7 days. More clinicians are electing to limit their antibiotic treatment regimen to 5 days as compelling data continue to support equal efficacy and possibly less side effects with short duration antibiotic therapy versus longer treatment regimens (>7 days).[42]

For the patient whose history suggests recurrent exacerbations of disease that might be attributable to specific events (e.g., seasonal or related to the winter months), a trial of prophylactic antibiotics might be beneficial. If no clinical improvement is noted over an appropriate period (2 to 3 months per year for 2 to 3 years), further attempts at prophylactic therapy can be discontinued. Similarly, patient-specific antibiotic trials can be performed in individuals experiencing acute exacerbations, focusing on attaining the maximum infection-free period. Although less than desirable,

this method of clinical assessment may distinguish patients who will benefit from prophylactic antibiotic therapy from those who will not.

BRONCHIOLITIS

EPIDEMIOLOGY AND ETIOLOGY

Bronchiolitis is an acute viral infection of the lower respiratory tract that affects approximately 50% of children during the first year of life and 100% by age 3 years. The occurrence of bronchiolitis peaks during the winter months and persists through early spring. Bronchiolitis remains the major reason for hospital admission during the first year of life. The incidence of bronchiolitis appears to be more common in males than in females.[43,44]

Respiratory syncytial virus (RSV) is the most common cause of bronchiolitis, accounting for up to 75% of all cases. During epidemic periods, the incidence of RSV-induced bronchiolitis may approach 90% of cases. Other detectable viruses include parainfluenza, adenovirus, and influenza. Bacteria serve as secondary pathogens in a minority of cases.[43,45]

CLINICAL PRESENTATION

A prodrome suggesting an upper respiratory tract infection, usually lasting from 2 to 8 days, precedes the onset of clinical symptoms (Table 116–4). Due to limited oral intake because of coughing combined with fever, vomiting, and diarrhea, infants frequently are dehydrated. The increased work of breathing and tachypnea most likely further increases fluid loss. In most cases, this clinical picture persists between 3 and 7 days. Although the hospital course of bronchiolitic children often is variable, substantial clinical improvement usually is observed within the first 2 days, with gradual improvement and complete resolution sometimes requiring 4 to 8 weeks.

The diagnosis of bronchiolitis is based primarily on history and clinical findings. It is important for the clinician to attempt to differentiate between bronchiolitis and a host of other clinical entities affecting infants, which may produce a similar picture of dyspnea and wheezing. Asthma, congestive heart failure, anatomic airway abnormalities, cystic fibrosis, foreign bodies, and gastroesophageal reflux are the primary disease entities that may present with wheezing in children. Isolation of a viral pathogen in the respiratory secretions of a wheezing child establishes a presumptive diagnosis of infectious bronchiolitis. However, the ability to identify specific viral pathogens often is hindered by the limited availability of special virology laboratories. In addition, in the elderly and in immunocompromised patients, antigen detection lacks adequate sensitivity, and patients frequently seek medical care after the acute stage of the infection, thus compromising the ability of the available tests to diagnose RSV. However, the proliferation of commercial enzyme-linked immunosorbent assays and fluorescent antibody staining techniques of nasopharyngeal secretions has increased the ability to identify viral antigens within several hours.[43] Identification of RSV by PCR should be available routinely from most clinical laboratories, but its relevance to the clinical management of bronchiolitis remains obscure.

Multiple clinical laboratory determinations have been used to assist in the management of cases of bronchiolitis. Radiographic evaluation of the chest in children with bronchiolitis yields variable findings but may help to distinguish this illness from other entities characterized by wheezing. In children requiring hospitalization, abnormalities in blood gas tensions are frequent and appear to relate to disease severity. Hypoxemia is common and increases the respiratory drive, whereas hypercarbia is seen in only the most severe cases. Despite the presence of moderate degrees of hypoxemia, clinical cyanosis is unusual.

TABLE 116-4 Clinical Presentation of Bronchiolitis

Signs and symptoms
Prodrome with irritability, restlessness, and mild fever
Cough and coryza
Vomiting, diarrhea, noisy breathing, and increased respiratory rate as symptoms progress
Labored breathing with retractions of the chest wall, nasal flaring, and grunting
Physical examination
Tachycardia and respiratory rate of 40–80 per minute in hospitalized infants
Wheezing and inspiratory rales
Mild conjunctivitis in one third of patients
Otitis media in 5–10% of patients
Laboratory tests
Peripheral white blood cell count normal or slightly elevated
Abnormal arterial blood gases (hypoxemia and, rarely, hypercarbia)

TREATMENT

Bronchiolitis

DESIRED OUTCOME

In the well infant, bronchiolitis usually is a self-limiting illness, and reassurance, antipyretics, and adequate fluid intake usually are all that are necessary while waiting for resolution of the underlying viral infection. In-hospital support is necessary for the child suffering from respiratory failure or marked dehydration; underlying cardiac and pulmonary diseases potentiate these conditions.

GENERAL APPROACH TO TREATMENT

Almost all otherwise healthy babies with bronchiolitis can be followed as outpatients. Such infants are treated for fever, provided generous amounts of oral fluids, and observed closely for evidence of respiratory deterioration.[46] In severely affected children, the mainstays of therapy for bronchiolitis are oxygen therapy and intravenous fluids. In a subset of patients, aerosolized bronchodilators may have a role. For selected infants, particularly those with underlying pulmonary disease, cardiac disease, or both, therapy with the antiviral agent ribavirin can be considered.[47]

PHARMACOLOGIC THERAPY

Aerosolized β_2-adrenergic therapy appears to offer little benefit for the majority of patients and may even be detrimental.[43,45] However, this therapy may offer some benefit to the child with a predisposition toward bronchospasm. In addition, although clinical trials have demonstrated varied results, nebulized epinephrine seems to be more efficacious than salbutamol in hospitalized patients with bronchiolitis.[43,48] For such patients, bronchodilator therapy may be offered initially but should not be pursued in the absence of a clear-cut clinical benefit. Similarly, controlled trials of corticosteroids in bronchiolitic infants have not shown therapeutic effects or significant harmful effects.[45,47] As a result, the routine use of systemically administered corticosteroids is discouraged. Conversely, the combined use of oral dexamethasone with nebulized epinephrine may act synergistically to reduce hospital admissions and shorten the time to discharge and the duration of symptoms; however, more trials are needed to confirm these findings.[49] Although placing

children with bronchiolitis in mist tents has been common practice, no data have documented the effectiveness of this practice.

Ribavirin may offer benefit to a subset of infants with bronchiolitis. Although ribavirin, a synthetic nucleoside, possesses in vitro antiviral properties against a variety of RNA and DNA viruses, including influenza A, influenza B, parainfluenza, and adenovirus,[45] it is approved only in aerosolized form against RSV. Use of the drug requires special equipment (small-particle aerosol generator) and specially trained personnel for administration via oxygen hood or mist tent. Special care must be taken to avoid drug particle deposition and the resulting clogging of respiratory tubing and valves in mechanical ventilators. Among hospital admissions for RSV infection, ribavirin therapy failed to decrease length of hospital stay, number of days in the intensive care unit, or number of days receiving mechanical ventilation. Consequently, the American Academy of Pediatrics has modified its recommendation for the use of ribavirin from "should be used" to "may be considered."[45] In light of this and because of the requirement for special aerosolization equipment and the cost of the drug itself, most experts recommend reserving use of ribavirin for severely ill patients, especially those with chronic lung disease (particularly bronchopulmonary dysplasia), congenital heart disease, prematurity, and immunodeficiency [especially severe combined immunodeficiency and human immunodeficiency virus (HIV) infection].

CLINICAL CONTROVERSY

Because bacteria are not primary pathogens in the etiology of bronchiolitis, antibiotics should not be administered routinely. Despite this, many clinicians frequently administer antibiotics while awaiting culture results because the clinical and radiographic findings in bronchiolitis often are suggestive of possible bacterial pneumonia.

For infants with underlying pulmonary or cardiovascular disease, prophylaxis against RSV may be warranted. When administered monthly during the RSV season, both RSV immune globulin[50] and palivizumab[51,52] (a monoclonal antibody for RSV) may decrease the number of RSV episodes and the need for hospitalization. Between the two, palivizumab appears to be preferred, given its ease of administration, lack of administration-related adverse effects, and noninterference with select immunizations.

There is no vaccine marketed for RSV. Of note, in the 1960s, a formalin-inactivated vaccine induced a promising IgG response; however, the severity of subsequent infections was increased in immunized patients. In addition, aside from the need to induce immunity to multiple strains of the virus, a series of boosters would be required as natural infection with RSV does not prevent subsequent infections.[47]

PNEUMONIA

EPIDEMIOLOGY

Pneumonia is the most common infectious cause of death in the United States, where approximately three million cases are diagnosed annually at a cost of more than $20 billion to the healthcare system.[53,54] Pneumonia occurs throughout the year, with the relative prevalence of disease resulting from different etiologic agents varying with the seasons. It occurs in persons of all ages, although the clinical manifestations are most severe in the very young, the elderly, and the chronically ill.

PATHOGENESIS

Microorganisms gain access to the lower respiratory tract by three routes. They may be inhaled as aerosolized particles, or they may enter the lung via the bloodstream from an extrapulmonary site of infection; however, aspiration of oropharyngeal contents, a common occurrence in both healthy and ill persons during sleep, is the major mechanism by which pulmonary pathogens gain access to the normally sterile lower airways and alveoli. When pulmonary defense mechanisms are functioning optimally, aspirated microorganisms are cleared from the region before infection can become established; however, aspiration of potential pathogens from the oropharynx can result in pneumonia if lung defenses are impaired.[1] Factors that promote aspiration, such as altered sensorium and neuromuscular disease, may result in an increase in the size of the inoculum delivered to the lower respiratory tract, thereby overwhelming local defense mechanisms. Lung infections with viruses suppress the antibacterial activity of the lung by impairing alveolar macrophage function and mucociliary clearance, thus setting the stage for secondary bacterial pneumonia. Mucociliary transport is also depressed by ethanol and narcotics and by obstruction of a bronchus by mucus, tumor, or extrinsic compression. All these factors can severely impair pulmonary clearance of aspirated bacteria.

8 The most prominent pathogen causing community-acquired pneumonia (CAP) in otherwise healthy adults is *S. pneumoniae* and accounts for up to 75% of all acute cases. Other common pathogens include *M. pneumoniae, Legionella species, C. pneumoniae, H. influenzae,* and a variety of viruses including influenza.[6,53,54] Healthcare-associated pneumonia (HCAP) has been a recently accepted classification used to distinguish nonhospitalized patients at risk for MDR pathogens [e.g., *P. aeruginosa, Acinetobacter species,* and methicillin-resistant *S. aureus* (MRSA)] from those with CAP.[6,55] The term *atypical* may be applied to pneumonia to indicate that the pneumonia may be caused by an atypical pathogen (e.g., bilateral lobar pneumonia with a negative Gram stain of sputum) caused by *M. pneumoniae, C. pneumoniae,* or *Legionella species.*[56]

Gram-negative aerobic bacilli, *S. aureus*, and MDR pathogens are the leading causative agents in hospital-acquired pneumonia (HAP).[7] Anaerobic bacteria are the most common etiologic agents in pneumonia that follows the gross aspiration of gastric or oropharyngeal contents. Ventilator-associated pneumonia (VAP) is also associated with MDR pathogens.

Pneumonia in infants and children is caused by a wider range of microorganisms, and, unlike adults, nonbacterial pathogens predominate. Most pneumonias occurring in the pediatric age group are caused by viruses, especially RSV, parainfluenza, and adenovirus.[45] *M. pneumoniae* is an important pathogen in older children. Beyond the neonatal period, *S. pneumoniae* is the major bacterial pathogen in childhood pneumonia, followed by group A *Streptococcus* and *S. aureus. H. influenzae* type b, once a major childhood pathogen, has become an infrequent cause of pneumonia since the introduction of active vaccination against this organism in the late 1980s.

Based on the differences in severity and outcome for patients with CAP, genetic factors likely play a role.[57] Multiple variations in genes affecting inflammation, cough and airway protection, pattern recognition molecules, and organ function along with environmental factors may alter a patient's response to CAP. In the future, as specific genetic polymorphisms are better associated with disease response, therapy should become better targeted.

TABLE 116-5 Clinical Presentation of Pneumonia

Signs and symptoms
Abrupt onset of fever, chills, dyspnea, and productive cough
Rust-colored sputum or hemoptysis
Pleuritic chest pain
Physical examination
Tachypnea and tachycardia
Dullness to percussion
Increased tactile fremitus, whisper pectoriloquy, and egophony
Chest wall retractions and grunting respirations
Diminished breath sounds over affected area
Inspiratory crackles during lung expansion
Chest radiograph
Dense lobar or segmental infiltrate
Laboratory tests
Leukocytosis with predominance of polymorphonuclear cells
Low oxygen saturation on arterial blood gas or pulse oximetry

CLINICAL PRESENTATION

Bacterial pneumonia is caused most commonly by gram-positive streptococci and staphylococci and gram-negative organisms that normally inhabit the gastrointestinal tract (enterics) and soil and water (nonenterics). In addition, *Legionella,* itself a weakly staining gram-negative nonenteric organism, accounts for a small percentage of community- and hospital-acquired bacterial pneumonia, although the true incidence may be underreported.[58] Finally, *M. tuberculosis,* an acid-fast staining bacillus, has reemerged as an important cause of pneumonia in urban centers throughout the United States.

A wide array of gram-positive and gram-negative organisms can cause pneumonia, but they usually present a similar clinical appearance (Table 116–5). *S. pneumoniae, S. aureus,* the enteric gram-negative rods, and occasionally other organisms may produce local irritation or destruction of blood vessels leading to rust-colored sputum or hemoptysis. Pleural effusions, both sterile and empyematous, may be associated with many of these entities, as evidenced by distant breath sounds and a wide area of dulled percussion. The chest radiograph and sputum examination and culture are the most useful diagnostic tests for gram-positive and gram-negative bacterial pneumonia. Typically, the chest radiograph reveals a dense lobar or segmental infiltrate. However, patchy consolidation may be seen occasionally with virtually all these pathogens. Occasionally, pneumonia resulting from hematogenous spread of the organisms results in a diffuse, alveolar pattern on chest radiograph. Gram stain of the expectorated sputum demonstrates many polymorphonuclear cells per high-powered field in the presence of a predominant organism, which is reflected as heavy growth of a single species on culture. Other laboratory tests are less sensitive or specific. Blood cultures may be helpful in identifying the offending organism but are positive in only a minority of patients. The complete blood count usually reflects a leukocytosis with a predominance of polymorphonuclear cells; in some instances, particularly with *S. pneumoniae*, elevation of the white blood cell (WBC) count may be pronounced. Normal or mildly elevated WBC counts, however, do not exclude bacterial pneumonic disease. The patient also may be hypoxic, as reflected by low oxygen saturation on arterial blood gas or pulse oximetry.

Although the clinical appearance of gram-positive and gram-negative pneumonias is similar, epidemiologic and clinical clues render one more likely than the other.

Community-Acquired Pneumonia

8 *S. pneumoniae* is the most common community-acquired bacterial pneumonia, accounting for up to 76% of cases.[54] It is particularly prevalent and severe for patients with splenic dysfunction, diabetes mellitus, chronic cardiopulmonary or renal disease, or HIV infection. Community-acquired disease with *S. aureus* is identified most frequently in young infants, patients with early cystic fibrosis, and those recovering from an antecedent respiratory viral infection. Group A *Streptococcus* is an uncommon cause of CAP and frequently occurs after a viral respiratory tract infection. Only occasionally is it associated with streptococcal pharyngitis. The organism is pyogenic, and the presentation can be severe. Community-acquired enteric gram-negative pneumonia is identified most frequently among patients with chronic illness, especially alcoholism and diabetes mellitus.

Severity scores, with varying strengths and weaknesses, have been utilized to assist healthcare professionals in predicting outcomes for patients with CAP.[59] Definitions of severe CAP may vary depending on the institution; however, patients with severe CAP are more likely to require intensive care, mechanical ventilation, or complications with sepsis, bacteremia, or multiorgan failure.[55] Severe CAP may be difficult to distinguish from HCAP or HAP; however, the pathogens, *S. pneumoniae*, *H. influenzae*, and anaerobic bacteria are not usually MDR. Patients at greater risk for severe CAP are those with underlying medical conditions or at risk for aspiration, animal exposure, or exposure to other infected patients or seasonal epidemics.[55]

Healthcare-Associated Pneumonia

Over the past several decades, the types of facilities where patients can receive healthcare has changed with infusion therapies, wound care, and dialysis available in an outpatient environment.[60] This, along with patients residing in a nursing home or long-term care facility or patients recently discharged from a hospital, has blurred the distinction between the pneumonia acquired as an inpatient versus an outpatient. See Table 116–6 for HCAP criteria. Patients diagnosed with HCAP are more similar to hospitalized patients based on comorbid conditions (e.g., heart disease, chronic kidney disease, immunocompromised, or dementia) than patients with CAP and are at a greater risk for multidrug-resistant pathogens.[7,55] The more common pathogens isolated from residents of long-term care facilities/nursing homes have MRSA, enteric gram-negative rods, and *Pseudomonas* species.[7] Compared with patients with CAP, patients with HCAP are more likely to receive inappropriate antibiotics initially and have a higher risk of mortality.[61] Thus, it is important to recognize the difference between HCAP and CAP for appropriate empiric antibiotics.

Pneumonia in the HIV-Infected Patient

HIV infects and destroys helper T lymphocytes bearing the CD4 surface molecule; these cells are critical for orchestrating a wide variety of immunologic responses. Their depletion consequently results in dysfunction of both cell-mediated and humoral immunity. As a result, a broad range of pathogens can cause pneumonia in HIV infection (Table 116–7).[62] The HIV-infected patient may be afflicted with pneumonia multiple times in his or her lifetime, particularly in the advanced stages of the disease, and a given episode may be caused by more than one species.

The clinical presentation of pneumonia in HIV-infected persons frequently is not helpful in distinguishing one pathogen from another. The pneumonia usually is subacute in onset and consists of fever, nonproductive cough, and dyspnea. Radiographically, most of these entities produce a multilobular or diffuse pattern. Some practitioners initially treat the HIV-infected patient with pneumonia empirically, covering the most common entities (bacteria and *P. jiroveci*). However, given the wide array of possible pathogens, more frequently a specific microbiologic diagnosis is aggressively

TABLE 116-6 Pneumonia Classifications and Risk Factors

Type of Pneumonia	Definition	Risk Factors
Community acquired (CAP)	Pneumonia developing in patients with no contact to a medical facility	• Age >65 years • Diabetes Mellitus • Asplenia • Chronic cardiovascular, pulmonary, renal and/or liver disease • Smoking and/or alcohol abuse
Healthcare associated (HCAP)	Pneumonia developing in patients not in medical facility but two or more risk factors for MDR pathogens	• Recent hospitalization ≥2 days within past 90 days • Nursing home or long-term care facility resident • Recent (past 30 days) antibiotic use, chemotherapy, wound care or infusion therapy either at a healthcare facility or home • Hemodialysis patients • Contact with a family member with infection caused by MDR pathogen
Hospital-acquired (HAP)	Pneumonia developing >48 hours after hospital admission	• Witnessed aspiration • COPD, ARDS, or coma • Administration of antacids or H2-antagonists • Supine position • Enteral nutrition, nasogastric tube • Reintubation, tracheostomy, or patient transport • Prior antibiotic exposure • Head trauma, ICP monitoring • Age >60 years • See healthcare associated for MDR risk factors
Ventilator associated (VAP)	Pneumonia developing >48 hours after intubation and mechanical ventilation	• Same as hospital acquired

TABLE 116-7 Pulmonary Complications of Human Immunodeficiency Virus Infection

- Infections
  - Viruses
    - Cytomegalovirus
    - Herpes simplex virus
    - Varicella-zoster virus
    - Respiratory syncytial virus and other common respiratory pathogens (parainfluenza virus, adenovirus)
    - Measles virus
  - Bacteria
    - Pyogenic organisms (especially *S. pneumoniae, H. influenzae*; in late disease, *S. aureus* and gram-negative organisms)
    - *M. tuberculosis*
    - *M. avium* complex and other nontuberculous mycobacteria
  - Fungi
    - *Histoplasma capsulatum*
    - *Coccidioides immitis*
    - *Cryptococcus neoformans*
    - *Candida* species
    - *Aspergillus* species
  - Parasites
    - *Pneumocystis carinii*
    - *Toxoplasma gondii*
    - Cryptosporidia
    - *Strongyloides stercoralis*
- Malignancies
  - Kaposi's sarcoma
  - Non-Hodgkin's lymphoma
  - Smooth muscle tumors
- Lymphocytic interstitial pneumonitis
- Nonspecific interstitial pneumonitis
- Drug-induced pneumonitis

From reference 63.

pursued early in the patient's course through sputum induction or bronchoalveolar lavage to allow a rational choice of an antimicrobial regimen. The diagnosis and treatment of HIV-infected patients with pulmonary disease is discussed in detail in Chap. 134.

Pneumonia in the Neutropenic Host

Neutropenia in the cancer patient is a common complication of aggressive chemotherapy but occasionally results from the cancer itself. The risk of infection for the cytopenic patient is increased significantly when the absolute neutrophil count falls below 500 cells/mm^3 and the neutropenia persists for more than 7 days.[63] For many patients, the duration of chemotherapy-induced cytopenia can be reduced by judicious application of colony-stimulating factors.[64]

The organisms that cause pneumonia in the cytopenic cancer patient include a broad range of bacteria and fungi. The most prominent among these are gram-positive bacteria (staphylococci and streptococci); others include enteric and nonenteric (particularly *P. aeruginosa*) gram-negative rods as well as the fungi (*Candida, Aspergillus).* The chest radiograph may reveal the lobar pattern typical of bacterial infection in the normal host, or it may exhibit a diffuse pattern. Sometimes the pneumonia remains invisible by chest radiograph until the neutropenia resolves. Noninfectious entities that may cause pulmonary symptoms include toxicity from radiation or chemotherapy or infiltration of the lung parenchyma by the tumor itself.

Hospital-Acquired Pneumonia

After the urinary tract and the bloodstream, the lungs are the most frequent site of infection acquired in the hospital. HAP is seen most commonly in critically ill patients and usually caused by bacteria.[7,65] Factors predisposing patients to the development of HAP include the severity of illness, duration of hospitalization, supine positioning, witnessed aspiration, coma, acute respiratory distress syndrome, patient transport, and prior antibiotic exposure (see Table 116–6).[66] The strongest predisposing factor, however, is mechanical ventilation (intubation). The length of stay for hospital admissions is increased, on average, by 7 to 9 days for patients who develop HAP.[7]

The organisms most commonly associated with HAP are *S. aureus* and enteric (e.g., *K. pneumoniae* or *E. coli*) and nonenteric (e.g., *P. aeruginosa*) gram-negative bacilli, organisms that colonize the pharynx of the hospitalized, critically ill patient. Patients with longer lengths of hospital admission prior to the development of HAP are more likely to have MDR organisms.[7] The diagnosis of HAP usually is established by the presence of a new infiltrate on chest radiograph, fever, worsening respiratory status, and the appearance of thick, neutrophil-laden respiratory secretions. In actuality, the diagnosis often is difficult to make in the intensively ill patient with underlying lung pathology that itself can be associated with an abnormal changing radiograph, as occurs with congestive heart failure or chronic lung disease. If patients develop fever, leukocytosis, purulent sputum, and have positive sputum/tracheal cultures but radiographic imaging does not indicate new infiltrates, the patient may have

tracheobronchitis as opposed to HAP.[7] Broad-spectrum antibiotics frequently are started empirically even in equivocal circumstances, with bronchoscopy reserved for poorly responsive patients.[7]

Gram-Positive Bacteria

S. aureus is a prominent cause of HAP and may result from hematogenous spread from a distant source. In both settings, it is characteristically severe and accompanied by the formation of pneumatoceles (air-containing cavities within the lung). Infections caused by MDR organisms such as MRSA and more recently vancomycin-intermediate and vancomycin-resistant *S. aureus* are increasing among patients with HAP. Group B *Streptococcus,* although rare in adults, is the most common cause of bacterial pneumonia among neonates, in whom it typically causes a clinical and radiographic picture nearly indistinguishable from hyaline membrane disease.[67]

Enteric Gram-Negative Bacteria

The enteric gram-negative bacteria are leading causes of HAP because the upper respiratory tract becomes rapidly colonized with gram-negative organisms after hospitalization, particularly among critically ill patients and those receiving antibiotics.[68] *K. pneumoniae* is the most frequently encountered pathogen among the gram-negative enteric bacteria, although the relative prominence of these organisms varies among hospitals. The gram-negative bacilli are associated with high mortality, sometimes exceeding 50%; their potential to produce significant morbidity and mortality has been enhanced by the emergence of highly MDR organisms in some hospital settings.[7]

Nonenteric Gram-Negative Bacteria

The most prominent nonenteric gram-negative rods associated with pneumonia include *P. aeruginosa, H. influenzae,* and *M. catarrhalis.* Like the enteric gram-negative organisms, *P. aeruginosa* is a frequent cause of HAP and is particularly prominent among neutropenic and burn patients.[7] In addition, cystic fibrosis patients suffer from chronic, multilobar infections with *P. aeruginosa* as well as other *Pseudomonas* species; these infections are punctuated with acute exacerbations.[69] *H. influenzae* type b historically has been a prominent pathogen in childhood pneumonia. However, the incidence of all invasive disease due to this organism in the pediatric age group has dropped dramatically since the introduction of the conjugated *Haemophilus* vaccines in the late 1980s. However, two different clinical presentations of *H. influenzae* pneumonia still are seen in adults. The most common by far is the bronchopneumonia form, which develops most frequently for patients with underlying chronic lung disease and is believed to represent, in most patients, an exacerbation of chronic bronchitis. In the second form of *H. influenzae* pneumonia, segmental or lobar involvement predominates. The course of this illness is more acute, with sudden onset of cough, fever, and pleuritic chest pain. Finally, *M. catarrhalis,* an important cause of otitis media and sinusitis, is an increasingly important cause of lower respiratory tract infections in immunoincompetent and hospitalized patients.

Anaerobic Bacteria

8 Anaerobic pneumonitis is most likely to occur in individuals predisposed to aspiration by impaired consciousness and may be more prevalent in those with periodontal disease or dysphagia. Bronchogenic carcinoma is an associated underlying condition. A variety of gram-positive and gram-negative anaerobic bacteria indigenous to the upper airway may cause pneumonitis when large quantities of oropharyngeal secretions are aspirated into the lower airways. The organisms most frequently implicated are *Peptostreptococcus* species, *Fusobacteria, B. melaninogenicus, B. fragilis,* and *Peptococcus* species; polymicrobial infections with anaerobes and aerobes, such as *S. aureus, S. pneumoniae,* and gram-negative bacilli, are common.[70]

The course of illness typically is indolent, with cough, low-grade fever, and weight loss, although an acute presentation may occur. Rigors are notably absent, and bacteremia is rare. Putrid sputum, when present, is highly suggestive of the diagnosis. Chest radiographs reveal infiltrates typically located in dependent lung segments, and lung abscesses develop in 20% of patients 1 to 2 weeks into the course of the illness.

Ventilator-Associated Pneumonia

VAP is defined as pneumonia occurring >48 hours post endotracheal intubation. The risk for developing pneumonia in the hospital increases by 6 to 21 times after a patient is intubated[7] because it bypasses the natural airway defenses against the migration of upper respiratory tract organisms into the lower tract. This situation is exacerbated by the wide use of H2-receptor blocking agents in the intensive care unit, which increases the pH of gastric secretions and may promote the proliferation of microorganisms in the upper gastrointestinal tract. Subclinical microaspirations are events that occur routinely in intubated patients and result in the inoculation of bacteria-contaminated gastric contents into the lung and a higher incidence of nosocomial pneumonia. VAP can be diagnosed accurately by any one of multiple standard criteria, including histopathologic examination of lung tissue obtained by open-lung biopsy, rapid cavitation of a pulmonary infiltrate in the absence of cancer or tuberculosis, positive pleural fluid culture, and same species with an identical antibiogram for a pathogen(s) isolated from blood and respiratory secretions without another identifiable source of bacteremia.[10] *P. aeruginosa* is the most common organism associated with VAP. Outbreaks of HAP may be caused occasionally by contaminated respiratory therapy equipment.

Atypical Pneumonia

Viruses, *Mycoplasma* species, *Chlamydia* species, and fungi are recognized causes of pneumonia syndromes in all age groups. The designation *atypical pneumonia,* distinct from the typical bacterial pneumonia seen most commonly in adults, has been used to describe the illness caused by many of these agents.[71]

Legionella Pneumophila

Of the several *Legionella* species known to cause pneumonia in humans, *L. pneumophila* is by far the most important, accounting for 2% to 15% of all CAPs in North America and Europe.[58] *Legionella* is a water and soil organism and most probably is transmitted by inhalation of aerosols containing the organism or by microaspiration of contaminated water. Outbreaks of illness caused by *L. pneumophila* have been linked to excavation sites and to contaminated water from air conditioners and showers. Person-to-person transmission has not been demonstrated. In addition to epidemics, *L. pneumophila* causes sporadic illness that peaks in summer and fall. Individuals who are male, middle aged or older, immunocompromised, chronic bronchitics, or cigarette smokers are at increased risk.

Infection with *L. pneumophila* is characterized by multisystem involvement, including rapidly progressive pneumonia.[71] It has a gradual onset, with prominent constitutional symptoms (e.g., malaise, lethargy, weakness, anorexia) occurring early in the course of the illness. A dry, nonproductive cough is present initially and becomes productive of mucoid or purulent sputum over several days. Fevers exceeding 40°C (104°F) develop in more than half of patients, typically are unremitting, and are associated with a

relative bradycardia. Pleuritic chest pain and progressive dyspnea may be seen. Extrapulmonary symptoms, particularly diarrhea, nausea, and vomiting, remain evident throughout the course of the illness. Myalgias and arthralgias also occur. Substantial changes in the patient's mental status, often out of proportion to the degree of fever, are seen in approximately one fourth of patients. Obtundation, hallucinations, grand mal seizures, and focal neurologic findings are also associated with this illness. Chest roentgenograms initially reveal patchy alveolar infiltrates that may be bilateral and asymmetric. Pulmonary infiltrates may worsen even when the patient is receiving appropriate antibiotics. Progression to lobar or multilobar consolidation is frequent, as are small pleural effusions.

Laboratory findings include leukocytosis with a predominance of mature and immature granulocytes in 50% to 75% of patients. Urinalysis may reveal proteinuria, hematuria, and casts; liver function tests may be abnormal. Hyponatremia and hypophosphatemia have been reported frequently. Because *L. pneumophila* stains poorly with commonly used stains, routine microscopic examination of sputum is of little diagnostic value. Although it exhibits slow growth and has highly selective growth requirements, *L. pneumophila* has been isolated successfully from tissue using a specialized medium. Direct fluorescent antibody examination of respiratory tract secretions, lung tissue, or pleural fluid is the most rapid means of establishing the diagnosis. The sensitivity of this method approaches 70% for sputum and 90% for lung tissue, and diagnostic specificity is high for both. Commercially available urine antigen tests have been developed for *L. pneumophila.* These tests are 70% sensitive and remain positive for weeks, even after effective antibiotics have been started. Because these diagnostic tests are unavailable in many clinical laboratories, the diagnosis of Legionnaires' disease often is presumptive and based on a suggestive clinical presentation.

Mycoplasma Pneumonia

Taxonomically, the mycoplasmas are included in their own class labeled *Mollicutes*. Although their small size and filterability are similar to viruses, the structure of their ribosomal RNA indicates that they have evolved from bacteria, and, unlike any virus, they contain cytoplasm and can replicate in an extracellular environment. They are distinguished from eubacteria by their low genetic content. In addition, the mycoplasmas lack a cell wall and are surrounded instead by a lipid membrane. This latter characteristic explains the resistance of these pathogens to cell-wall active antibiotics.

M. pneumoniae causes human disease throughout the year, with a slightly increased incidence in fall and early winter. During the summer months when other causes of pneumonia are less common, *M. pneumoniae* is responsible for a greater proportion of cases. Both infection and disease from *M. pneumoniae* are common, with two thirds of children ages 2 to 5 years and 97% of persons older than 17 years having detectable serum antibody to the organism. Overall, *M. pneumoniae* is responsible for approximately 20% of pneumonia cases, although in enclosed populations, such as military recruits and college dormitory residents, it may cause more than 50%. Infection is spread by close person-to-person contact, and the incubation period is 2 to 3 weeks. *M. pneumoniae* infections are unusual in children younger than 5 years and show a peak incidence in older children and young adults. Only 3% to 10% of persons infected with *M. pneumoniae* develop pneumonia, with the majority of respiratory tract involvement manifested as pharyngitis and tracheobronchitis. Asymptomatic infection is common.

M. pneumoniae usually presents with a gradual onset of fever, headache, and malaise, with the appearance 3 to 5 days after the onset of illness of a persistent, hacking cough that initially is nonproductive. Sore throat, ear pain, and rhinorrhea often are present. Chills are seen only occasionally, and pleuritic pain is uncommon. Lung findings generally are limited to rales and rhonchi; findings of consolidation are rare. Nonpulmonary manifestations are extremely common and include nausea, vomiting, diarrhea, myalgias, arthralgias, polyarticular arthritis, skin rashes, myocarditis and pericarditis, hemolytic anemia, meningoencephalitis, cranial neuropathies, and Guillain-Barré syndrome. Systemic symptoms generally clear in 1 to 2 weeks, whereas respiratory symptoms may persist for up to 4 weeks. Although the course of mycoplasmal pneumonia usually is benign and self-limited, severe respiratory disease may develop in patients with sickle cell disease, agammaglobulinemia, and COPD.[71]

Radiographic findings generally are more impressive than the patient's physical findings and include patchy or interstitial infiltrates, which are seen most commonly in the lower lobes. Small unilateral, transient pleural effusions are common, but large effusions and empyema are rare. Roentgenographic abnormalities resolve slowly, and 4 to 6 weeks may be required for complete resolution.

Sputum Gram stain may reveal mononuclear or polymorphonuclear leukocytes, with no predominant organism. Although *M. pneumoniae* can be cultured from respiratory secretions using specialized medium, its growth is slow, and 2 to 3 weeks may be necessary for culture identification. Indirect evidence of infection by *M. pneumoniae* is the presence of elevated levels of serum cold hemagglutinins. These immunoglobulin M antibodies develop in approximately half of patients with mycoplasmal pneumonia and can be elevated in other illnesses, especially viral infection. A definitive diagnosis also can be made by demonstrating a fourfold or greater rise in serum antibodies to *M. pneumoniae.* However, because this test also requires 2 to 4 weeks for results, the diagnosis of mycoplasmal pneumonia during the acute phase of the illness must be based on the characteristic history, appropriate clinical setting, and typical physical findings.

Chlamydophila Pneumonia

C. pneumoniae has received the new taxonomic classification of *Chlamydophila;* however, it may still be referred to as *Chlamydia pneumoniae* in some references.[16] *C. pneumoniae,* formally designated the *TWAR* agent after the laboratory designations for the first two isolates, is antigenically similar to *C. psittaci. C. pneumoniae* infection is ubiquitous worldwide, but only a small percentage of infections result in clinically apparent pneumonia. Conversely, approximately 5% to 15% of pneumonia is associated with this pathogen.[16] Primary infection with *Chlamydia* pneumonia typically occurs in young adults and is characterized by mild respiratory symptoms with a gradual onset. Constitutional manifestations, particularly fever and headache, are common. The radiographic findings are nonspecific and usually consist of multilobular interstitial infiltrates. Immunity is incomplete, and reinfection with *C. pneumoniae* is common, particularly among the elderly. Definitive diagnosis of *C. pneumoniae*–associated pneumonia depends on identification of the organism in sputum. Culture of this organism is difficult, and commercially available antigen detection systems are insensitive.

Viral Pneumonia

Viruses are an uncommon cause of pneumonia in adults, except in the immunosuppressed.[3] Influenza virus, usually type A, is the most common cause of pneumonia in the adult civilian population causing CAP;[6] adenoviruses cause most cases in military trainees. In contrast, viruses are by far the most common agents producing pneumonia in infants and young children, with RSV, parainfluenza, and adenovirus producing most cases.[7,43]

All viral respiratory tract infections occur more commonly in the winter, and rapid person-to-person spread through susceptible populations is typical. Underlying cardiac or pulmonary disease predisposes to an increased incidence and severity of viral lower respiratory tract infection, especially with influenza virus in adults and RSV in children. Radiographic findings are nonspecific and include bronchial wall thickening and perihilar and diffuse interstitial infiltrates. Pleural effusions may be seen, especially in adenovirus and parainfluenza pneumonia.

The clinical pictures produced by respiratory viruses are sufficiently variable and overlap to such a degree that an etiologic diagnosis can not be made confidently based on clinical grounds alone. Although virus isolation in tissue culture is possible, a period of 7 or more days often is required for virus identification; thus, this method usually cannot be used for definitive diagnosis during the acute phase of illness. Serologic tests for virus-specific antibodies are used often in the diagnosis of viral infections. The diagnostic fourfold rise in titer between acute and convalescent phase sera may require 2 to 3 weeks to develop. Same-day diagnosis of viral infections now is possible using indirect immunofluorescence tests on exfoliated cells from the respiratory tract. The immunofluorescence technique frequently uses a battery of monoclonal antibodies, including those against influenza A and B, RSV, parainfluenza, and adenovirus, to provide rapid diagnosis of a range of viral infections.[3]

Tuberculosis

The acid-fast bacillus *M. tuberculosis* causes tuberculosis. After years of steady decline, the number of cases of pneumonia caused by *M. tuberculosis* in the United States began to increase in the middle to late 1980s. The new epidemic was a consequence of an increased incidence among prison inmates, intravenous drug abusers, immigrants, and, most prominently, HIV-infected patients.[72] It is most prominent in urban neighborhoods afflicted with crowded conditions and poor access to healthcare. Unlike previous eras in which tuberculosis was seen most frequently in elderly men, infection currently is identified in increasing numbers of young minority adults. As mentioned, the resurgence of tuberculosis is at least partially related to coinfection with HIV; HIV-infected patients are more likely to develop symptomatic disease with its associated fits of coughing than are their immunocompetent counterparts, and this enables further spread of infection. Other groups prone to tuberculosis include the homeless and patients in chronic care facilities and homes for the elderly. Fortunately, since 1992, the incidence of tuberculosis in the United States has declined, reaching a record low. However, the incidence of tuberculosis worldwide continues to increase. Both the sustained worldwide increase in tuberculosis and the reemergence of tuberculosis in the United States are important reasons for the development of multiple-drug resistance, that is, mycobacteria that are resistant to two or more of the first-line antituberculosis drugs. Infection caused by these organisms is poorly responsive to alternative therapy and is associated with mortality rates exceeding 50% (see Chap. 121).

Tuberculosis is spread from person to person by inhalation of droplet nuclei generated by vigorous coughing. Adult disease (from adolescence onward) begins with constitutional complaints, followed by a prominent chronic, troublesome cough productive of mucopurulent material. The infection initially appears in the lung apices with little or no hilar adenopathy and, in advanced disease, results in lung necrosis, producing a cavity containing enormous numbers of organisms. In contrast, pediatric tuberculosis commonly is associated with little cough even in the presence of extensive pulmonary infection. Instead, the child presents with a subacute course of poor appetite, weight loss, lethargy, fever, and sweats.

Severe Acute Respiratory Syndrome

In November 2002, an extremely contagious atypical pneumonia manifested in China that since has been termed *severe acute respiratory syndrome* (SARS).[73] The etiology of SARS is an enveloped RNA virus, a coronavirus, referred to as SARS-CoV. The virus is transmitted primarily via large-droplet spread; however, surface contamination and airborne and fecal spread are possible. Signs and symptoms associated with SARS include high fever, myalgias, headache, diarrhea, and a dry nonproductive cough. Respiratory symptoms may progress to shortness of breath and hypoxemia, necessitating the need for intubation and mechanical ventilation. Diagnostic tests for patients suspected of contracting SARS should include chest x-ray film, blood cultures, sputum cultures and Gram stain, pulse oximetry, and identification of other potential pathogens, including influenza A and B, *Legionella,* and RSV. For unclear reasons, SARS appears to be less severe for pediatric patients.

Avian Influenza (Bird Flu)

All influenza viruses may be present in aquatic birds, with the H5N1 subtype being extremely pathogenic and fatal to fowl.[74,75] The first known cases of humans infected with this subtype occurred in Hong Kong in 1997, with 6 deaths among 18 infected patients. Signs and symptoms typical of the H5N1 virus are those common to other subtypes and include conjunctivitis, fever, rhinitis, and pharyngitis. However, pneumonia, respiratory distress syndrome, lymphopenia, and clotting abnormalities tend to occur rapidly in patients infected with this highly virulent subtype. Laboratory tests used to detect the H5N1 virus include immunoassays and reverse-transcription PCR.

H1N1 Influenza (Swine Flu)

In April 2009, a novel influenza A virus of swine origin, H1N1, was identified as the causative pathogen in a recent outbreak of respiratory illness and influenza-like illness in Mexico.[76] Due to a report of atypical pneumonia and an increase in the number of respiratory illnesses in North America, surveillance increased that resulted in the WHO raising alert status to phase 6, global pandemic, in June 2009. Signs and symptoms of the H1N1 virus are similar to other subtypes and include fever, cough, sore throat, body and headaches, chills, and fatigue; however, more serious infections have resulted in hospitalization and death. It has also affected normally healthy young adults as opposed to other flu viruses, which tend to be more severe in the young and the elderly. Transmission of the virus is thought to be similar to seasonal flu and spread via coughing, sneezing, and touching infected objects. PCR diagnostic kits have been developed to facilitate the detection of the virus.

TREATMENT

Pneumonia

DESIRED OUTCOME

Eradication of the offending organism through selection of the appropriate antibiotic and complete clinical cure are the goals of therapy for bacterial pneumonia. Therapy should minimize associated morbidity, including one or both of the following: reversible or irreversible disease and drug-induced organ toxicity (e.g., renal, lung, or hepatic dysfunction). Most cases of viral pneumonia are self-limiting, although therapy of influenza pneumonia with specific antiviral agents (oseltamivir and zanamivir) may hasten recovery. All efforts should focus on the design of the most cost-effective

approach to therapy. Whenever possible, the oral (vs parenteral) route for drug administration should be selected, encouraging outpatient management rather than hospitalization.

GENERAL APPROACH TO TREATMENT

9 The first priority in assessing the patient with pneumonia is to evaluate the adequacy of respiratory function and to determine the presence of signs of systemic illness, specifically dehydration or sepsis with resulting circulatory collapse. Oxygen or, in severe cases, mechanical ventilation and fluid resuscitation should be provided as necessary. Further supportive care of the patient with pneumonia includes humidified oxygen for hypoxemia, administration of bronchodilators (albuterol) when bronchospasm is present, and chest physiotherapy with postural drainage if evidence of retained secretions is present. Additional therapeutic adjuncts include adequate hydration (intravenously if necessary), optimal nutritional support, and control of fever. Appropriate sputum samples may be obtained to determine the microbiologic etiology. Rehydration should be provided to replace losses that may have occurred as a result of fever, poor intake, and/or associated vomiting. Selection of an appropriate antimicrobial must be made based on the patient's probable or documented microbiology, distribution in the respiratory tract, side effects, and cost. Respiratory track infection diagnosis and treatment guideline reports have been published by authoritative professional organizations that focus on proper treatment regimens and should be consulted for evidence-based treatment recommendations across the spectrum of community- and/or hospital-associated pneumonias.[77,78]

PHARMACOLOGIC THERAPY

Antibiotic Concentrations

Antibiotic concentrations in respiratory secretions in excess of the pathogen MIC are necessary for successful treatment of pulmonary infections.[78,79] The concept of a blood–bronchus barrier, analogous but dissimilar to the blood–brain barrier, has been used to assess the characteristics of drug penetration into pulmonary secretions. The ability of a drug to penetrate respiratory secretions depends on multiple physicochemical factors, including molecular size, lipid solubility, and degree of ionization at serum and biologic fluid pH and extent of protein binding. Studies performed in animals and cystic fibrosis patients suggest that larger molecular size favors the accumulation of drugs in bronchial secretions. This finding contrasts with data on drug penetration of other physiologic compartments, such as the cerebrospinal fluid, and may be a result of the trapping of lower-molecular-weight compounds in mucin pores. Nevertheless, the rate at which a drug may accumulate in certain respiratory secretions appears to remain an important factor relative to the drug's clinical efficacy in treating pulmonary infections. The un-ionized form of drug and lipid solubility also appears to favor drug penetration. Of note, the pH of the infected bronchi often is more acidic than that of normal tissue and blood. These factors combined underscore the importance of considering the inhaled route of antimicrobial drugs for the treatment of patients with moderate to severe pneumonia, particularly in high-risk patient groups.[79–81]

Limited data are available for assessing the influence of drug protein binding on the rate and amount of respiratory secretion penetration. Clearly, it is the free antibiotic fraction reaching the infected site capable of binding to the bacterial cell target that is responsible for antibacterial activity. Given that the degree of protein binding influences a drug's ability to traverse membranes, a similar relationship would be expected within the lung. However, focusing on the absolute amount of an antibiotic bound to plasma/tissue proteins without accounting for the drug's overall antibacterial potency is errant. To completely assess an antibiotic's therapeutic potential in the treatment of pneumonia or any infectious process, it is prudent to assess the antibiotic's integrated pharmacokinetic–pharmacodynamic (PK-PD) characteristics (e.g., bacterial killing may be concentration dependent or time dependent) that account for the drug's degree of binding to serum proteins, tissue distribution, and in vitro potency. Thus, simply focusing on a drug's degree of protein binding is an errant, overly simplistic approach that does not account for the drug's inherent antibacterial activity or distribution characteristics.

These concepts relating to antibiotic activity and overall drug penetration of respiratory secretions underscore the importance of applying the advances realized in our knowledge of antimicrobial PK and PD to the design of optimal antibiotic dosing regimens. Integration of an individual antimicrobial drug's PK-PD has afforded the development of just such optimal antibiotic dosing regimens (improved efficacy and safety) based upon drug- and patient-specific factors.[77,78] A primary example of antibiotic PK-PD designed optimal dosing is reflected in the clinical practice of administering certain antibiotics (aminoglycosides) to achieve high peak serum concentrations on the assumption that higher (and possibly more effective) biologic fluid concentrations of the drug will be achieved. The aminoglycosides are large polar molecules that diffuse poorly into tissue and respiratory secretions; however, with increasing concentrations obtained with once-daily dosing, increased target-tissue concentrations would be expected with increasing individual doses. Further, recognizing that the peak drug concentration-to-pathogen MIC ratio (Cmax:MIC) is the primary PK-PD correlate for aminoglycosides and that the target Cmax:MIC ratio for aminoglycosides is ~10, the single daily dose strategy is most likely to achieve the desired PK-PD target at the desired anatomic site. Similarly for the so-called respiratory fluoroquinolones (e.g., levofloxacin, moxifloxacin, gemifloxacin) higher individual dose therapy targeting a greater Cmax:MIC ratio or the more commonly targeted area under the concentration time curve (AUC) to pathogen MIC ratio, i.e.,AUC:MIC, for fluoroquinolones. The target 24 hour AUC:MIC ratio for fluoroquinolones is 35+ (possible minimum of 25) for gram-positive and 125+ (possible minimum of 100) for gram-negative pathogens. For greatest probability of success, the antibiotic concentrations projected in these PK-PD correlates should include the expected free (not protein bound) antibiotic concentration. Conversely, concentration-dependent killing characteristics best correlate with successful therapy with the β-lactam/carbapenem and macrolide classes of antimicrobials.[77,78]

Sputum is frequently assessed as possibly representing the PD interface for pulmonary infections. Sputum is only one of many pulmonary fluids and secretions, and it may serve as a reservoir for pathogen growth. These beliefs have led many investigators to assess antibiotic concentrations in sputum, frequently describing sputum drug concentrations as a ratio of serum to sputum drug concentration. Although sputum drug concentrations provide some insight into the characteristics of drug penetration of respiratory secretions, caution should be exercised in the interpretation of these data. Data describing sputum drug concentrations often are difficult to interpret because of differences in analytic techniques, method of sputum sampling, and random nature of sampling times relative to drug dose. Moreover, representation of sputum drug concentrations as a ratio of serum drug concentration can be misleading and most probably should be described relative to absolute drug concentration or apparent area under the drug concentration versus time curve in sputum. To more accurately describe the distribution characteristics of antimicrobial agents in sputum, research studies should be designed to allow sequential repeated sputum

sampling over a specified dosage interval under both first-dose and steady-state conditions. Thus, until greater sophistication is achieved in our understanding of the relationships between antibiotic concentrations in specific anatomic sites, plasma (blood)-based integrated PK-PD correlates should be used for antibiotic and dose selection.

Selection of Antimicrobial Agents

Treatment of bacterial pneumonia, like the treatment of most infectious diseases, initially involves the empirical use of a relatively broad-spectrum antibiotic that is effective against probable pathogens after appropriate cultures and specimens for laboratory evaluation have been obtained.[6,7,82] Therapy should be narrowed to cover specific pathogens after the results of cultures are known. Multiple factors that help to define the potential pathogens involved include patient age, previous and current medication history, underlying disease(s), major organ function, and present clinical status. These factors must be evaluated to select an appropriate and effective empirical antibiotic regimen as well as the most appropriate route for drug administration (oral or parenteral). For a more detailed discussion on the principles of antibiotic selection, see Chap. 114.

Numerous antibiotics are available, and many are effective in the treatment of bacterial pneumonia. Superiority of one antibiotic over another when both demonstrate similar dose-normalized in vitro activity and tissue distribution characteristics is difficult to define. Our opinions on appropriate empirical choices for the treatment of bacterial pneumonias relative to a patient's underlying disease are listed in Table 116–8 for adults and Table 116–9 for children. A complete listing of antimicrobial agents for specific pathogens is beyond the scope of this chapter and is presented in Chap. 114.

A patient's previous medical history of responding/not responding to one of these antibiotics in the recent past will assist greatly in the decision to continue their use. In contrast and for patients with risk factors, regardless of the patient's setting at the time of infection, i.e., community, long-term care facility, acute care hospital, etc., the fluoroquinolone antibiotics represent important treatment tools based on their highly favorable PK (tissue and intracellular distribution) and PD (potency, broad spectrum) characteristics combined with ease of administration (IV, oral) and patient tolerability. Furthermore, optimal dosing directed by the projected 24 hour free fluoroquinolone AUC-to-pathogen MIC ratio (see above) has markedly decreased the emergence of pathogen resistance, fostered maximal bacteriologic kill and enhanced patient safety.

Table 116–10 lists dosages for selected antibiotics used for the treatment of bacterial pneumonia. The list of commercially available antimicrobial agents with documented bacterial and clinical effectiveness in the treatment of pneumonia can appear endless.

TABLE 116-8 Evidence-Based Empiric Antimicrobial Therapy for Pneumonia in Adults[a]

Clinical Setting	Usual Pathogens	Empiric Therapy
Outpatient/community acquired		
• Previously healthy	*S. pneumoniae, M. pneumoniae, H influenza, C. pneumoniae, M. catarrhalis*	Macrolide/azalide[b], or tetracycline[c]
• Comorbidities (diabetes, heart/lung/liver/ renal disease, alcoholism		Fluoroqinolone[d] or β-lactam + macrolide[b]
• Elderly	S. pneumoniae, Gram-negative bacilli	Piperacillin/tazobactam or cephalosporin[e] or carbapenem[f]
Inpatient/community acquired		
• Non-ICU	*S. pneumoniae, H. influenza, M. pneumoniae, C. pneumoniae, Legionella* sp.	Fluoroquinolone[d] or β-lactam + macrolide[b]
• ICU	*S. pneumoniae, S.aureus, Legionella* sp, gram-negative bacilli, *H. influenza*	β-lactam + macrolide[b] or fluoroquinolone[d]; piperacillin/taxobactam or meropenem or cefepime + fluoroquinolone[d], or β-lactam + AMG + azithromycin or β-lactam + AMG + respiratory fluoroquinolone[d]
	If MRSA suspected	Above + vancomycin or linezolid
Hospital acquired, ventilator associated, or healthcare associated		
• No risk factors for MDR pathogens	*S. pneumoniae, H. influenzae*, MSSA enteric Gram-negative bacilli	Ceftriaxone or fluoroquinolone[d] or ampicillin/sulbactam or ertapenem or doripenem
• Risk factors for MDR pathogen	*P. aeruginosa, K. pneumoniae* (ESBL), Acinetobacter sp.,	Antipseudomonal cephalosporin[e] or antipseudomonal carbapenem or β-lactam/β-lactamase + antipseudomonal fluoroquinolone[d] or AMG[g]
	If MRSA or Legionella sp. suspected	Above + vancomycin or linezolid
• Aspiration	Mouth anaerobes, *S. aereus*, enteric Gram-negative bacilli	Penicillin or clindamycin or piperacillin/tazobactum + AMG[g]
Atypical pneumonia[h]		
• *Legionella pneumophilia*		Fluoroquinolone[d] or doxycycline
• *Mycoplasma pneumonia*		Fluoroquinolone[d] or doxycycline
• *Chlamydophila pneumonia*		Fluoroquinolone[d] or doxycycline
• SARS		Fluoroquinolone[d] or macrolides[b]
• Avian Influenza		Oseltamivir
• H1N1 Influenza		Oseltamivir

MRSA, methicillin resistance staphylococcus aureus; AMG, aminoglycoside; SARS, severe acute respiratory syndrome; ESBL, extended-spectrum β-lactamases.
[a]See section on treatment of bacterial pneumonia
[b]Macrolide/azalide: erythromycin, clarithromycin, azithromycin
[c]Tetracycline: tetracycline, HC1, doxycycline
[d]Fluoroquinolone: ciprofloxacin, levofloxacin, moxifloxacin
[e]Antipseudomonal cephalosporin: cefepime, ceftazidime
[f]Antipseudomonal carbapenem: imipenem, meropenem
[g]Aminoglycoside: amikacin, gentamicin, tobramycin
[h]For tuberculosis, see Chap. 121.
Data from references 6 and 7.

TABLE 116-9 Empirical Antimicrobial Therapy for Pneumonia in Pediatric Patients[a]

Age	Usual Pathogen(s)	Empirical Therapy
1 month	Group B streptococcus, *H. influenzae* (nontypeable), *E. coli, S. aureus, Listeria*, CMV, RSV, adenovirus	Ampicillin/sulbactam, cephalosporin,[b] carbapenem[c]
		Ribavirin for RSV[g]
1–3 months	*C. pneumoniae*, possibly *Ureaplasma*, CMV, *Pneumocystis carinii* (afebrile pneumonia syndrome)	Macrolide/azalide,[d] trimethoprim-sulfamethoxazole
	RSV	Ribavirin
	S. pneumoniae, *S. aureus*	Semisynthetic penicillin[e] or cephalosporin[f]
3 months to 6 years	*S. pneumoniae*, *H. influenzae*, RSV, adenovirus, parainfluenza	Amoxicillin or cephalosporin[f]
		Ampicillin/sulbactam, amoxicillin–clavulanate
		Ribavirin for RSV
>6 years	*S. pneumoniae*, *M. pneumoniae*, adenovirus	Macrolide/azalide[d]
		cephalosporin,[f] amoxicillin–clavulanate

CMV, cytomegalovirus; RSV, respiratory syncytial virus.
[a]See section on treatment of bacterial pneumonia.
[b]Third-generation cephalosporin: ceftriaxone, cefotaxime, cefepime. Note that cephalosporins are not active against *Listeria*.
[c]Carbapenem: imipenem–cilastatin, meropenem.
[d]Macrolide/azalide: erythromycin, clarithromycin/azithromycin.
[e]Semisynthetic penicillin: nafcillin, oxacillin.
[f]Second-generation cephalosporin: cefuroxime, cefprozil.
[g]See text for details regarding ribavirin treatment for RSV infection.

TABLE 116-10 Antibiotic Doses for Treatment of Bacterial Pneumonia

		Daily antibiotic dose[a]	
Antibiotic Class	**Antibiotic**	***Pediatric (mg/kg/day)***	***Adult (Total Dose/ Day)***
Macrolide	Clarithromycin	15	0.5–1 g
	Erythromycin	30–50	1–2 g
Azalide	Azithromycin	10 mg/kg × 1 day, then 5 mg/kg/day 4 days	500 mg day 1, then 250 mg/day × 4 days
Tetracycline[b]	Doxycycline	2–5	100–200 mg
	Tetracycline HCl	25–50	1–2 g
Penicillin	Ampicillin	100–200	2–6 g
	Amoxicillin ± clavulanate[c]	40–90	0.75–1 g
	Piperacillin/ tazobactam	200–300	12–18 g
	Ampicillin/ sulbactam	100–200	4–8 g
Extended-spectrum cephalosporins	Ceftriaxone	50–75	1–2 g
	Ceftazidime	150	4–6 g
	Cefepime	100–150	2–6 g
Fluoroquinolones[d]	Moxifloxacin		400 mg
	Gemifloxacin	–	320 mg
	Levofloxacin	10–15	0.75 g
	Ciprofloxacin	20–30	1.2 g
Aminoglycosides	Gentamicin	7.5–10	7.5 mg/kg
	Tobramycin	7.5–10	7.5 mg/kg
Carbapenems	Imipenem	60–100 g	2–4 g
	Meropenem	30–60	1–3 g
Other	Vancomycin	45–60	2–3 g
	Linezolid	20–30	1.2 g

[a]Doses can be increased for more severe disease and may require modification for patients with organ dysfunction.
[b]Tetracyclines are rarely used in pediatric patients, particularly in those younger than 8 years because of tetracycline-induced permanent tooth discoloration.
[c]Higher-dose amoxicillin, amoxicillin/clavulanate (e.g., 90 mg/kg/day) is used for penicillin-resistant *S. pneumoniae*.
[d]Fluoroquinolones have been avoided for pediatric patients because of the potential for cartilage damage; however, they have been used for MDR bacterial infection safely and effectively in infants and children (see text).

The large number of expensive drugs mandates critical evaluation for formulary selection and clinical use. Similarities of in vitro activity, resistance to bacterial-inactivating enzymes, and overall effectiveness often make rational therapeutic decisions difficult and even appear random. However, some general principles can be applied to guide rational antibiotic choice, including direct comparison of the antibiotic's likely attainment of the defined PK-PD target correlate for specific bacterial species within the infected site. These PK-PD principals are outlined above. An understanding and application of inherent drug characteristics appears to be of the utmost importance for the selection of an optimal therapeutic regimen. Thus, whenever possible, identification of the causative pathogen and expected/defined antibiotic activity (e.g., MIC) is of paramount importance to the selection/design of the optimal antibiotic regimen.

Community-Acquired Pneumonia

Table 116–8 provides evidence-based guidelines for the treatment of CAP.[6] The bacterial causes are relatively constant, even across geographic areas and patient populations. Unfortunately, pathogen resistance to standard antimicrobials is increasing (e.g., penicillin-resistant pneumococci), necessitating careful attention by the clinician to local and regional bacterial susceptibility patterns.[53] Thus, whenever possible, initial therapy should be based on presumed antibacterial susceptibility and consist of older, less-expensive agents, with newer and more expensive antibiotics reserved for unresponsive illness or special circumstances. Indiscriminate use of recently introduced agents increases healthcare costs and, in some instances (e.g., widespread use of fluoroquinolones), induces resistance among a significant percentage of community-acquired organisms.[6] It must be emphasized, however, that the rapidly evolving epidemiology of bacterial resistance, including the increasing emergence of penicillin-resistant *S. pneumoniae* in many areas of the United States and Europe, forces the clinician to be vigilant and knowledgeable about antibiotic sensitivity patterns in each community. Indiscriminate use of antimicrobials for treatment of pneumonia has contributed to the problem of antimicrobial resistance, underscoring the need for defining the optimal antibiotic regimen for each patient.

9 Evidence-based empirical therapy differs among outpatients, hospitalized patients, and hospitalized patients admitted to an intensive care unit (Table 116–8).[6,83,84] Antimicrobial therapy should be initiated for hospitalized patients with acute pneumonia within 8 hours of admission because an increase in mortality has been demonstrated when therapy was delayed beyond 8 hours of admission.

Healthcare-Associated Pneumonia

It is important to identify patients at risk for HCAP and initiate appropriate empiric antibiotic therapy since these patients are at risk for MDR organisms. Delaying treatment of appropriate antibiotics in these patients increases mortality.[55] Antibiotic selection will be similar to those used in HAP and VAP. Broad spectrum antibiotics should be used empirically for pneumonia developing ≥5 days after hospital admission or if the patient has risk factors for MDR pathogens.[7] See Table 116–8 for recommended empiric antimicrobial therapy.

Hospital-Acquired Pneumonia

⑩ Antibiotic selection within the hospital environment demands greater care because of constant changes in antibiotic resistance patterns in vitro and in vivo. Ironically, some β-lactam antibiotics, which were developed to treat MDR hospital-acquired organisms, can themselves induce broad-spectrum bacterial β-lactamases and thereby lead to even greater problems with resistance.[85] These facts underscore the importance of regularly documenting the epidemiology of pathogens and infectious diseases within a specific practice or institution. As a result, an antimicrobial agent for a specific infectious disease favored in one practice site may not be the most desirable selection in another site despite similarities in size and patient profile. Strict and careful control and, possibly, rotation of empirical antibiotics in the hospital environment may help to limit the emergence of resistant organisms. Newer antibiotics developed for treatment of resistant, hospital-acquired pathogens are costly; therefore, their use must be moderated to some extent in an era where capitated hospital costs and mandated budget cuts will not tolerate careless antibiotic use. Broad spectrum antibiotics are more appropriate choices for patients with risk factors for MDR pathogens or if HAP develops after at least 5 days of hospitalization.[7] See Table 116–8 for recommended antimicrobial therapy.

Ventilator-Associated Pneumonia

The approach to treating VAP is similar to antibiotic selection in HAP and HCAP (see Table 116–8). Patients should be carefully evaluated to determine whether they are at risk for MDR pathogens as this is essential in selecting appropriate empiric antibiotic therapy.[7] It is also important to identify patients with VAP early since delays in initiating appropriate antibiotic therapy are associated with increased mortality. Aerosolized antibiotic delivery has been considered for more targeted therapy; however, there are limited studies at this time supporting the safety and efficacy in pneumonia.[86]

CLINICAL CONTROVERSY

Prior to the availability of newer β-lactam and fluoroquinolone antibiotics possessing consistently potent activity against multiple gram-negative pathogens, some investigators promoted the administration of antibiotics by direct endotracheal instillation. This method of drug administration attempts to provide increased topical concentrations of antibiotics that do not appear to penetrate respiratory secretions effectively while reducing the likelihood of systemic toxicity. In addition, greater local concentrations of antibiotics, particularly of the polymyxins and aminoglycosides, are believed to overcome partially the substantial decrease in antibiotic bioactivity observed when these agents interact with the purulent material present in infectious foci. Despite these potential theoretical advantages, the role of antibiotic aerosols or direct endotracheal instillation in clinical practice remains controversial.[78–82]

Atypical Pneumonia

Pneumonia caused by atypical pathogens may be more difficult to treat with antibiotics than "typical" pathogens. It is debatable whether empiric treatment for hospitalized patients with CAP should include antibiotic coverage of atypical pathogens. Currently there does not appear to be any benefit in terms of survival or clinical efficacy to providing atypical coverage for all patients.[87]

For *Legionella* pneumonia, fluoroquinolones are superior to macrolides, the previous drug of choice.[88] *Mycoplasma* pneumonia is difficult to treat due to the organism's lack of a cell wall, limiting certain antibiotics, and is found on epithelial cells in the respiratory tract instead of inside the cells.[71] Macrolides and tetracyclines are generally effective against *Mycoplasma*. *Chlamydophila* organisms are sensitive to macrolides, doxycycline, and fluoroquinolones. For viral causes of pneumonia, antivirals such as amantadine and oseltamivir can be used, depending on viral susceptibility. Management of TB is discussed in Chap. 121. See Table 116–8 for a summary of the evidence-based guidelines on management.

Severe Acute Respiratory Syndrome

Treatment of SARS involves primarily supportive care and procedures to prevent transmission to others.[73] Owing to the uncertainty associated with the diagnosis of SARS, empirical therapy with broad-spectrum antibiotics should be used. To date, fluoroquinolones (e.g., moxifloxacin, levofloxacin) or macrolides/azalides (e.g., erythromycin, clarithromycin, azithromycin) typically have been used. Although its efficacy is unproven, ribavirin also has been used to treat patients. Owing to the potential benefit of corticosteroids in the presence of progressive pulmonary disease, methylprednisolone has been used in doses ranging from 80 to 500 mg/day.

Avian Influenza

Treatment of avian influenza is primarily supportive, with the majority of patients requiring aggressive oxygen therapy and intensive care monitoring.[74,75] Due to observed resistance with amantadine, the neuraminidase inhibitors are the recommended treatment of avian influenza, with oseltamivir being the preferred agent. For optimal efficacy, treatment should be initiated within 48 hours of the first sign of infection. Of note, there is concern regarding oseltamivir, with a resistant A/H5N1 isolate identified in Vietnam.[75]

H1N1 Influenza (Swine Flu)

Treatment of H1N1 influenza is primarily supportive, with the majority of patients being treated as outpatients. The H1N1 virus is currently susceptible to oseltamivir and zanamivir and resistant to amantadine and rimantadine. Therefore, antivirals should only be administered to patients at high risk for influenza complications (i.e., hospitalized patients and those at high risk for seasonal flu complications). Vaccinations are being developed for H1N1 virus.

PREVENTION

Prevention of some cases of pneumonia is possible through the use of vaccines and medications against selected infectious agents. Polyvalent polysaccharide vaccines are available for two of the leading causes of bacterial pneumonia, *S. pneumoniae* and *H. influenzae* type b. In addition, evidence-based guidelines for preventing HCAP have been published (Table 116–11).[89] (See Chap. 118 for a full discussion of prevention of influenza and Chap. 133.)

EVALUATION OF THERAPEUTIC OUTCOMES

After therapy has been instituted, appropriate clinical parameters should be monitored to ensure the efficacy and safety of the therapeutic regimen. For patients with bacterial infections of the upper or lower respiratory tract, the time to resolution of initial presenting symptoms and the lack of appearance of new associated symptomatology are important to determine. For patients with CAP or pneumonia from any source of mild to moderate clinical severity, the time to resolution of cough, decreasing sputum production, and

TABLE 116-11 Evidenced-Based Guidelines for Preventing Healthcare-Associated Pneumonia

Recommendation	Recommendation Grade[a]
For nebulizers, use aerosolized medications in single-dose vials. If multidose medication vials are used, follow manufacturers' instructions for handling, storing, and dispensing the medications.	1B
Pneumococcal vaccination is recommended for patients at high risk for severe pneumococcal infections.	1A
Unless contraindicated, administer a macrolide to any person who has had close contact with persons having pertussis.	1B
In acute-care settings, offer vaccine to inpatients and outpatients at high risk for complications from influenza beginning in September and throughout the influenza season.	1A
Unless contraindicated, provide prophylactic treatment to all patients without influenza illness in the involved unit with amantadine, rimantadine, or oseltamivir for a minimum of 2 weeks or until approximately 1 week after the end of the outbreak.	1A
Unless contraindicated, patients with influenza should receive amantadine, rimantadine, oseltamivir, or zanamivir within 48 hours of the onset of symptoms.	1A

[a]Grade IA, strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies; grade IB, strongly recommended for implementation and supported by certain clinical or epidemiologic studies and by strong theoretical rationale.

fever, as well as other constitutional symptoms of malaise, nausea, vomiting, and lethargy, should be noted. If the patient requires supplemental oxygen therapy, the amount and need should be assessed regularly. A gradual and persistent improvement in the resolution of these symptoms and therapies should be observed. Initial resolution should be observed within the first 2 days and progression to complete resolution within 5 to 7 days but usually no more than 10 days. For patients with HAP/HCAP, substantial underlying diseases, or both, additional parameters can be followed, including the magnitude and character of the peripheral blood WBC count, chest radiograph, and blood gas determinations. Similar to patients with less severe disease, some resolution of symptoms should be observed within 2 days of instituting antibiotic therapy. If no resolution of symptoms is observed within 2 days of starting seemingly appropriate antibiotic therapy or if the patient's clinical status is deteriorating, the appropriateness of initial antibiotic therapy should be critically reassessed. The patient should be evaluated carefully for deterioration of underlying concurrent disease(s). Additionally, the caregiver should consider the possibility of changing the initial antibiotic therapy to expand antimicrobial coverage not included in the original regimen (e.g., *Mycoplasma, Legionella,* and anaerobes). Furthermore, the need for antifungal therapy (lipid-based amphotericin B) should be considered. Some resolution of symptoms should be observed within 2 days of starting proper antibiotic therapy, with complete resolution expected within 10 to 14 days.

ABBREVIATIONS

CAP: community-acquired pneumonia

COPD: chronic obstructive pulmonary disease

HAP: hospital-acquired pneumonia

HCAP: healthcare-associated pneumonia

MDR: multidrug resistant

MIC: minimum inhibitory concentration

MRSA: methicillin-resistant *S. aureus*

PCR: polymerase chain reaction

PK-PD: pharmacokinetic–pharmacodynamic

RSV: respiratory syncytial virus

SARS: severe acute respiratory syndrome

VAP: ventilator-associated pneumonia

WBC: white blood cell

CHAPTER 117

Upper Respiratory Tract Infections

CHRISTOPHER FREI, BRADI FREI, AND GEORGE ZHANEL

KEY CONCEPTS

1. Most upper respiratory tract infections have a viral etiology and tend to resolve spontaneously without pharmacologic therapy.
2. The most common bacterial causes are *Streptococcus pneumoniae* (acute otitis media and acute sinusitis) and group A β-hemolytic *Streptococcus* (acute pharyngitis).
3. Vaccination against influenza and pneumococcus may decrease the risk of acute otitis media.
4. Because upper respiratory tract infections are so common, antibiotics used to treat them serve as catalysts for the emergence and spread of antibiotic resistance, thereby making prudent antibiotic use critically important.
5. When antibiotics are prescribed, the empiric medications of choice are amoxicillin for acute otitis media and acute sinusitis and penicillin for acute pharyngitis.
6. For otitis media, high-dose amoxicillin (80–90 mg/kg/day) is recommended if the patient is at high risk for a penicillin-resistant pneumococcal infection.

Patients visit medical clinics and emergency rooms more for upper respiratory tract infections than any other reason.[1,2] Otitis media, sinusitis, and pharyngitis are the three most common upper respiratory tract infections. Other, less common infections are laryngitis, rhinitis, and epiglottitis. Because they are so common, community and emergency healthcare workers must be familiar with the diagnosis, assessment, and management of these infections. Furthermore, antibiotics used for the treatment of upper respiratory tract infections serve as catalysts for the emergence and spread of antibiotic resistance, thereby making prudent antibiotic use critically important.

ACUTE OTITIS MEDIA

The term *otitis media* comes from the Latin *oto-* for "ear," *-itis* for "inflammation," and *medi-* for "middle;" otitis media, then, is an inflammation of the middle ear. There are three subtypes of otitis media: acute otitis media, otitis media with effusion, and chronic otitis media. The three are differentiated by onset, signs and symptoms of infection, and the presence of fluid in the middle ear.[3,4] Acute otitis media is the subtype with the greatest role for antibiotics and will be discussed in detail.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

Otitis media is the 11th most common reason for an emergency room visit and the 15th most common reason for an office visit in the United States, accounting for more than 15 million emergency room and clinic visits annually.[1,2] It is common in infants and children, 75% of whom will have at least one episode in the first 12 months of life.[5] More than 80% of patients seen for acute otitis media receive a prescription, and the direct and indirect costs associated with managing otitis media add up to almost $3 billion annually in the United States.[3]

ETIOLOGY

1 Approximately 40% to 75% of acute otitis media cases are caused by viral pathogens.[3] 2 Common bacterial pathogens include *Streptococcus pneumoniae* (25–50%), nontypeable *Haemophilus influenzae* (15–30%), and *Moraxella catarrhalis* (3–20%).[3] The microbial etiology may be changing as a result of the introduction and widespread use of the pneumococcal conjugate vaccine. Specifically, the proportion of *S. pneumoniae* cases may be declining, and the proportion of *H. influenzae* cases may be on the rise.[6,7]

S. pneumoniae, H. influenzae, and *M. catarrhalis* can all possess resistance to β-lactams. *S. pneumoniae* develops resistance through alteration of penicillin-binding proteins, whereas *H. influenzae* and *M. catarrhalis* produce β-lactamases.[3] Between 15% and 50% of *S. pneumoniae* isolates from the upper respiratory tract are not susceptible to penicillin, and up to half of these have high-level penicillin resistance.[8] Half of the *H. influenzae* and 100% of *M. catarrhalis* isolates from the upper respiratory tract produce β-lactamases.[9]

The risk factors for amoxicillin-resistant bacteria in acute otitis media are attendance at child care centers, recent receipt of antibiotic treatment (within the past 30 days), and age younger than 2 years.[3]

PATHOPHYSIOLOGY

Acute bacterial otitis media usually follows a viral upper respiratory tract infection that causes eustachian tube dysfunction and mucosal swelling in the middle ear.[10] The middle ear is the space behind the tympanic membrane, or eardrum. A noninfected ear has a thin, clear tympanic membrane. In otitis media, this space becomes blocked with fluid, resulting in a bulging and erythematous tympanic membrane. Bacteria that colonize the nasopharynx enter the middle ear and are not cleared properly by the mucociliary system.[11]

The bacteria proliferate and cause infection.[10,11] Children tend to be more susceptible to otitis media than adults because the anatomy of their eustachian tube is shorter and more horizontal, facilitating bacterial entry into the middle ear.[10]

CLINICAL PRESENTATION

Patients or caregivers frequently characterize acute otitis media as having an acute onset of ear pain. For parents of young children, irritability and tugging on the ear are often the first clues that a child has acute otitis media. The diagnosis of acute otitis media and otitis media with effusion are easily confused, and careful attention to history, signs, and symptoms is important. Otitis media with effusion is characterized by fluid in the middle ear without signs and symptoms of acute ear infection, such as pain and a bulging eardrum.[4]

A diagnosis of acute otitis media requires that three criteria be satisfied: acute onset of signs and symptoms, middle ear effusion, and middle ear inflammation.[3] Middle ear effusion is indicated by any of the following: bulging of the tympanic membrane, limited or absent mobility of the tympanic membrane, air-fluid level behind the tympanic membrane, or otorrhea.[3] Signs and symptoms of middle ear inflammation include either distinct erythema of the tympanic membrane or distinct ear otalgia (or ear pain).[3] A diagnosis is considered to be "uncertain" if the patient does not have all three of these diagnostic criteria.

CLINICAL PRESENTATION OF ACUTE BACTERIAL OTITIS MEDIA

General

- Acute onset of signs and symptoms of middle ear infection following cold symptoms of runny nose, nasal congestion, or cough

Signs and Symptoms

- Ear pain that can be severe (>75% of patients)
- Children may be irritable, tug on the involved ear, and have difficulty sleeping
- Fever is present in less than 25% of patients and, when present, occurs more often in younger children
- Examination shows a discolored (gray), thickened, bulging eardrum
- Pneumatic otoscopy or tympanometry demonstrates an immobile eardrum; 50% of cases are bilateral
- Draining middle ear fluid occurs in less than 3% of patients and usually has a bacterial etiology

Laboratory Tests

- Gram stain, culture, and sensitivities of draining fluid or aspirated fluid if tympanocentesis is performed

Adapted from Hendley JO. Clinical practice: Otitis media. N Engl J Med 2002;347(15):1169–1174.

TREATMENT

DESIRED OUTCOME

6 Treatment goals include pain management, prudent antibiotic use, and secondary disease prevention. These will be discussed in detail, but first, it is important to consider primary prevention of acute otitis media through the use of bacterial and viral vaccines.

3 A systematic review demonstrated that the seven-valent pneumococcal conjugate vaccine Prevnar (with CRM197 carrier protein) reduced the occurrence of acute otitis media episodes by 6% to 7% when the vaccine was administered during infancy.[12] Other, currently nonlicensed pneumococcal conjugate vaccines had mixed results. Children with a history of acute otitis media did not benefit when the seven-valent vaccine was administered at an older age.[12] An *H. influenzae* type b (Hib) vaccine is now available and reduces invasive Hib disease;[13] however, it is the nontypeable *H. influenzae* that is of greatest concern in acute otitis media. Other vaccines, including nontypeable *H. influenzae* and *M. catarrhalis* vaccines, are in development. Finally, because acute otitis media cases often follow influenza cases, influenza vaccination should be considered as a possible means to prevent acute otitis media. Refer to the U.S. Centers for Disease Control and Prevention website (*www.cdc.gov*) and statements from the Advisory Committee on Immunization Practices (ACIP) for the most up-to-date information regarding recommended pneumococcal and influenza immunization practices.[14,15]

GENERAL APPROACH TO TREATMENT

The first step in the treatment of otitis media is to differentiate acute otitis media from otitis media with effusion or chronic otitis media, as the latter two types do not benefit substantially from antibiotic therapy. The second step is to address pain with oral analgesics. The third step is to consider if a brief observation period is warranted or if the disease severity or patient characteristics require immediate antibiotic therapy. If a bacterial infection is suspected, consider if the patient has risk factors for penicillin resistance. Recognize that amoxicillin is the mainstay of therapy and that penicillin resistance can be overcome, in many cases, with high-dose amoxicillin therapy. The therapeutic strategy should be changed if complications develop or if symptoms fail to resolve within 3 days.

NONPHARMACOLOGIC THERAPY

Regardless of the decision to administer antibiotics, acetaminophen or a nonsteroidal antiinflammatory drug (NSAID), such as ibuprofen, should be offered early to relieve pain in acute otitis media.[3] In addition, eardrops with a local anesthetic, such as ametocaine, benzocaine, or lidocaine, provide pain relief when administered with oral pain medication to children ages 3 to 18 years.[16] Because of minimal benefit and increased side effects, neither decongestants nor antihistamines should be routinely recommended in cases of acute otitis media or otitis media with effusion.[3,4,17,18]

PHARMACOLOGIC THERAPY

National clinical practice guidelines for appropriate diagnosis and treatment of acute otitis media were first published in 2004 by the American Academy of Pediatrics (AAP) and the American Academy of Family Physicians (AAFP).[3] Three pertinent systematic reviews have also been released.[19–21] The AAP/AAFP guidelines for acute otitis media are focused on children 2 months through 12 years of age with uncomplicated cases. These guidelines do not pertain to children with systemic illness or with underlying conditions that may alter the course of acute otitis media (e.g., anatomic abnormalities, genetic conditions such as Down syndrome, immunodeficiencies, and cochlear implants).[3]

3 Antibiotic therapy for upper respiratory diseases must be balanced with possible increases in adverse drug events and increased antibiotic pressure. One strategy to reduce antibiotic use in this setting is "delayed therapy."[22] Delayed therapy most often means that a healthcare worker provides the patient with a prescription

but encourages the patient to wait to use the medication for 48 to 72 hours to see if the symptoms will resolve on their own. Candidates for delayed therapy include (a) children 6 months to 2 years of age without severe symptoms plus uncertain diagnosis, (b) children 2 years and older without severe symptoms, and (c) children 2 years and older with an uncertain diagnosis.[3] Delayed therapy decreases antibiotic use but also decreases patient satisfaction. Ultimately, this strategy is no better than avoiding antibiotics altogether.[22]

4 5 If antibiotics are to be administered, then amoxicillin should be given to most children, at a dose of 80 to 90 mg/kg/day.[3] *S. pneumoniae* resistance to penicillin can be overcome with this high amoxicillin dose. If pathogens that produce β-lactamase are known or suspected, then amoxicillin should be given in combination with a β-lactamase inhibitor: amoxicillin-clavulanate at a dose of 90 mg/kg/day of amoxicillin with 6.4 mg/kg/day of clavulanate in two divided doses.[23]

Clinical trials have not provided a clear answer as to which antibiotics are most efficacious;[24] therefore, the choice of amoxicillin is largely based on microbiology and pharmacokinetic-pharmacodynamic studies. Amoxicillin has the best pharmacodynamic profile against drug-resistant *S. pneumoniae* of all available oral antibiotics. In addition, amoxicillin has a long record of safety, possesses a narrow spectrum, and is inexpensive. Higher middle ear fluid concentrations of amoxicillin as a result of higher dosing overcome most drug-resistant *S. pneumoniae* even with its increased minimum inhibitory concentration (MIC).[25] Its excellent efficacy against *S. pneumoniae* outweighs the issue of β-lactamase-producing *H. influenzae* and *M. catarrhalis,* against which amoxicillin may not be effective. This is because *H. influenzae* and *M. catarrhalis* are both more likely than *S. pneumoniae* to lead to a spontaneous resolution of the infection. In patients with moderate to severe illness (temperature >39°C [102°F] and/or severe otalgia), amoxicillin-clavulanate is recommended. Table 117–1 lists antibiotic recommendations for acute otitis media.

If treatment failure occurs with amoxicillin, an antibiotic should be chosen with activity against β-lactamase-producing *H. influenzae* and *M. catarrhalis,* as well as drug-resistant *S. pneumoniae.*[10] High-dose amoxicillin-clavulanate is recommended. Other choices are cefuroxime, cefdinir, cefpodoxime, and intramuscular ceftriaxone.[3] Second-generation cephalosporins, though β-lactamase stable, are expensive, have an increased incidence of side effects, and may increase selective pressure for resistant bacteria. Furthermore, most cephalosporins do not achieve adequate middle ear fluid concentrations against drug-resistant *S. pneumoniae* for the desired duration of the dosing interval. Use of trimethoprim-sulfamethoxazole and erythromycin-sulfisoxazole is discouraged because of high rates of resistance.[3] Intramuscular ceftriaxone is the only antibiotic other than amoxicillin that achieves middle ear fluid concentrations above the MIC for >40% of the dosing interval.[26] Although single doses of ceftriaxone have been used, daily doses for 3 days are recommended to optimize clinical outcomes.[3,10] Ceftriaxone should be reserved for severe and unresponsive infections or for patients for whom oral medication is inappropriate because of vomiting, diarrhea, or possible nonadherence. Ceftriaxone is an expensive antibiotic, and the intramuscular injections are painful. The drug can be given intravenously, but the risk-to-benefit ratio of starting an IV line must also be examined. Tympanocentesis can also be considered for treatment failure or persistent acute otitis media. It has a therapeutic effect of relieving pain and pressure and can be used to collect fluid to identify the causative agent. Clindamycin may also be considered at this point for coverage of documented penicillin-resistant *S. pneumoniae.*[3] Patients with a penicillin allergy can be treated with several alternative antibiotics. If the reaction is not type I hypersensitivity, cefdinir, cefpodoxime, or cefuroxime can be used.[3] If the reaction is type I, a macrolide such as azithromycin or clarithromycin may be used. If *S. pneumoniae* is documented, clindamycin is an alternative. However, the incidence of resistance is much higher with these antibiotics,[10] and of these antibiotics, only clindamycin is recommended by the AAP guidelines.[3]

There is debate regarding the optimal duration of therapy for acute otitis media. Traditional recommendations were for 10 to 14 days of antibiotic therapy; however, 5 days of therapy may be as effective as 10 days.[27] The advantages of short-term therapy are an increased likelihood the patient will adhere to the full course of treatment, decreased side effects and cost, and decreased bacterial-selective pressure for both the individual and the community. Short treatment courses in children younger than 2 years are not recommended.[25] In children at least 6 years old who have mild to moderate acute otitis media, a 5- to 7-day course may be used.

Recurrent acute otitis media is defined as at least three episodes in 6 months or at least four episodes in 12 months. Recurrent infections are of concern because patients younger than 3 years are at high risk for hearing loss and language and learning disabilities.[28] Data from studies generally do not favor prophylaxis. A meta-analysis demonstrated that prophylaxis prevents one infection each time one child is treated for 9 months.[29] Of further concern is antibiotic resistance. Treatment can be delayed until the onset of symptoms of an upper respiratory tract infection (viral symptoms), or antibiotic prophylaxis can be limited to 6 months' duration during the winter months. Surgical insertion of tympanostomy tubes (T-tubes) is an effective method for the prevention of recurrent

TABLE 117-1 Acute Otitis Media Antibiotic Recommendations

	Initial Diagnosis		Failure at 48–72 Hours	
	Nonsevere	**Severe**[a]	**Nonsevere**	**Severe**[a]
First line	Amoxicillin, high-dose; 80–90 mg/kg/day divided twice daily	Amoxicillin-clavulanate, high-dose;[b] 90 mg/kg/day of amoxicillin plus 6.4 mg/kg/day of clavulnate divided twice daily	Amoxicillin-clavulanate, high-dose;[b] 90 mg/kg/day of amoxicillin plus 6.4 mg/kg/day of clavulanate divided twice daily	Ceftriaxone (1–3 days)
Non–type 1 allergy	Cefdinir, cefuroxime, cefpodoxime	Ceftriaxone (1–3 days)	Ceftriaxone (1–3 days)	Clindamycin
Type 1 allergy	Azithromycin, clarithromycin		Clindamycin	Clindamycin

[a]Severe = temperature ≥39°C (102°F) and/or severe otalgia.
[b]Amoxicillin-clavulanate 90:6.4 or 14:1 ratio is available in the United States; 7:1 ratio is available in Canada (use amoxicillin 45 mg/kg for one dose, amoxicillin 45 mg/kg with clavulanate 6.4 mg/kg for second dose).
Adapted from McCaig LF, Nawar EW. National Hospital Ambulatory Medical Care Survey: 2004 emergency department summary. Adv Data 2006(372):1–29.

otitis media. These small tubes are placed through the inferior portion of the tympanic membrane under general anesthesia and aerate the middle ear. Children with recurrent acute otitis media should be considered for T-tube placement. Finally, there may be an emerging role for oral fluoroquinolones when acute otitis media does recur or persist.

CLINICAL CONTROVERSY

Fluoroquinolones have not been used extensively in acute otitis media because of concerns regarding the safety of these antibiotics when used in children. This is primarily due to animal studies in which juvenile laboratory animals experienced cartilage lesions in weight-bearing joints.[80] However, the concern for β-lactam resistance has prompted some to investigate the safety and efficacy profile of oral fluoroquinolones in children with acute otitis media. Three studies by a single group of investigators with oral fluoroquinolone used in children with recurrent or persistent acute otitis media demonstrated similar efficacy compared with amoxicillin-clavulanate.[81–83] None demonstrated more frequent adverse drug effects with fluoroquinolones compared with amoxicillin-clavulanate, although these studies were underpowered to evaluate uncommon adverse effects, such as cartilage lesions. On July 8, 2008, the United States Food and Drug Administration (FDA) strengthened the fluoroquinolone labeling by adding a boxed warning concerning the "increased risk of developing tendinitis and tendon rupture in patients taking fluoroquinolones for systemic use."

PHARMACOECONOMIC CONSIDERATIONS

Pharmacoeconomic considerations are minimal in the treatment of acute otitis media, as the medications of choice are widely available from several generic manufacturers. There is some debate regarding the cost-effectiveness of routine recommendations for childhood influenza and pneumococcal immunization as a means to reduce acute otitis media.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients with acute otitis media should be reassessed after 3 days. Pain and fever tend to resolve after 2 or 3 days, with most children becoming asymptomatic at 7 days. Treatment failure is a lack of clinical improvement in the signs and symptoms of infection, including pain, fever, and erythema/bulging of the tympanic membrane, after 3 days. If antibiotics were withheld initially, they should be instituted now. If the patient initially received an antibiotic, then the antibiotic should be changed (Table 117–1).

Early reevaluation of the eardrum when signs and symptoms are improving can be misleading because effusions persist. Over a period of 1 week, changes in the eardrum normalize, and the pus becomes serous fluid. Air-fluid levels are apparent behind the eardrum, at which point the stage is now referred to as *otitis media with effusion.* This does not represent ongoing infection, nor are additional antibiotics required. Two weeks after an acute otitis media episode, 60% to 70% of children still have a middle ear effusion; 40% at 1 month, and 10% to 25% at 3 months.[3] Younger children and those with a history of recurrent infections have a further delay in resolution.[11] Immediate reevaluation is appropriate if hearing loss results from persistent middle ear effusions following infection.[4] Complications of otitis media are infrequent but include mastoiditis, bacteremia, meningitis, and auditory sequelae with the potential for speech and language impairment.[3,4]

ACUTE BACTERIAL SINUSITIS

Sinusitis is an inflammation and/or infection of the paranasal sinuses, or membrane-lined air spaces, around the nose.[30,31] The term *rhinosinusitis* is used by some specialists because sinusitis typically also involves the nasal mucosa.[30] Even though the majority of these infections are viral in origin, antibiotics are prescribed frequently. It is thus important to differentiate between viral and bacterial sinusitis to aid in optimizing treatment decisions. This chapter will focus on acute bacterial sinusitis.

EPIDEMIOLOGY

More than 31 million cases of sinusitis are diagnosed annually in the United States.[32] 1 Most sinusitis infections have a viral etiology; nevertheless, sinusitis accounts for 9% and 21% of all adult and pediatric antibiotic prescriptions, respectively.[33] Acute bacterial sinusitis is overdiagnosed by family physicians; thus, antibiotics are overprescribed.[30,34] Children have six to eight viral upper respiratory tract infections per year, yet only 5% to 13% of these are complicated by a secondary bacterial sinusitis infection.[35] Only 0.5% to 2% of viral upper respiratory tract infections in adults are complicated by sinusitis.[30,31,35] Ultimately, sinusitis results in 5.8 billion expenditures annually in the United States.[36]

ETIOLOGY

Viruses are responsible for most cases of acute sinusitis; however, when symptoms persist for 7 days or more or become severe, bacteria may be a primary or secondary cause of infection.[30] 2 Acute bacterial sinusitis is caused most often by the same bacteria implicated in acute otitis media: *S. pneumoniae* and *H. influenzae.* These organisms are responsible for ~70% of bacterial causes of acute sinusitis in both adults and children.[33] *M. catarrhalis* is also frequently implicated in children (~25%).[33,35] *Streptococcus pyogenes, Staphylococcus aureus,* fungi, and anaerobes are associated less frequently with acute sinusitis.[30,33] Issues of bacterial resistance are similar to those found with otitis media.

PATHOPHYSIOLOGY

Similar to acute otitis media, acute bacterial sinusitis usually is preceded by a viral respiratory tract infection that causes mucosal inflammation.[30,31,35] This can lead to obstruction of the sinus ostia—the pathways that drain the sinuses. Mucosal secretions become trapped, local defenses are impaired, and bacteria from adjacent surfaces begin to proliferate. The maxillary and ethmoid sinuses are the ones most frequently involved. The pathogenesis of chronic sinusitis has not been well studied. Whether it is caused by more persistent pathogens or there is a subtle defect in the host's immune function, some patients develop chronic symptoms after their acute infection.

CLINICAL PRESENTATION

The greatest barrier to efficient use of antibiotics in acute bacterial sinusitis is the lack of a simple and accurate diagnostic test. The gold standard for the diagnosis of acute bacterial sinusitis is sinus puncture with recovery of bacteria in high density ($\geq 10^4$ colony-forming units/mL);[30,35] however, sinus puncture is an invasive procedure, so it is not routinely done. Sinus radiography can help, but it is not routinely recommended for uncomplicated sinusitis.

Because there is no simple and accurate office-based test for acute bacterial sinusitis, clinicians rely on clinical findings to make the diagnosis.

In general, patients with acute bacterial sinusitis present with nonspecific upper respiratory symptoms that persist for 7 to 14 days. Children may have nasal discharge, cough, fever (>39°C [>102°F]), and facial or sinus swelling and/or pain. Likewise, adults may have nasal congestion or discharge, maxillary tooth pain, facial or sinus swelling and/or pain, and fever. For chronic sinusitis, symptoms are similar, but they may be even more nonspecific. Chronic sinusitis patients may also have chronic unproductive cough, laryngitis, or headache.

CLINICAL PRESENTATION AND DIAGNOSIS OF BACTERIAL SINUSITIS

General

- A nonspecific upper respiratory tract infection that persists beyond 7 to 14 days

Signs and Symptoms

- Acute
  - *Adults*
    - Nasal discharge/congestion
    - Maxillary tooth pain, facial or sinus pain that may radiate (unilateral in particular), as well as deterioration after initial improvement
    - Severe or persistent (>7 days) signs and symptoms are most likely bacterial and should be treated with antibiotics
  - *Children*
    - Nasal discharge and cough for longer than 10 to 14 days or severe signs and symptoms such as temperature above 39°C (102°F) or facial swelling or pain are indications for antibiotic therapy
- Chronic
  - Symptoms are similar to acute sinusitis but more nonspecific
  - Rhinorrhea is associated with acute exacerbations
  - Chronic unproductive cough, laryngitis, and headache may occur
  - Chronic/recurrent infections occur three or four times per year and are unresponsive to steam and decongestants

Laboratory Tests

- Gram stain, culture, and sensitivities of draining fluid or aspirated fluid if sinus puncture is performed

TREATMENT

DESIRED OUTCOME

The goals of treatment for acute sinusitis are to reduce signs and symptoms, achieve and maintain patency of the ostia, limit antibiotic treatment to those who may benefit, eradicate the bacterial infection with appropriate antibiotic therapy, minimize the duration of illness, prevent complications, and prevent progression from acute disease to chronic disease.[33,35]

GENERAL APPROACH TO TREATMENT

A clinical practice guideline outlined 17 action statements for the management of sinusitis, 7 of which pertain to acute bacterial sinusitis.[37,38] The cumulative evidence behind all seven recommendations was assigned a grade of B, indicating that the evidence came from "randomized controlled trials or diagnostic studies with minor limitations or overwhelmingly consistent evidence from observational studies." See Table 117–2 for abbreviated definitions of the terms used to describe this evidence and Table 117–3 for the actual evidence-based statements.

The first step in the assessment and treatment of sinusitis is to delineate viral and bacterial sinusitis. This is based on disease duration, rather than symptomatology, as signs and symptoms are generally similar for viral and bacterial sinusitis. Viral sinusitis typically improves in 7 to 10 days; therefore, a diagnosis of acute bacterial sinusitis requires persistent symptoms (≥10 days) or a worsening of symptoms after 5 to 7 days. Bacterial sinusitis may also be suspected if symptoms do not respond to nonprescription nasal decongestants and acetaminophen.

If a bacterial infection is suspected, the next step is to decide whether the infection is complicated or uncomplicated. Acute bacterial sinusitis is considered to be complicated if the patient has mental status changes, immunosuppressive illness, unilateral findings, significant coexisting illnesses, risk factors for β-lactam-resistant strains, history of antibiotic failure, isolated frontal or sphenoid sinusitis, or intense periorbital swelling, erythema, and facial pain. When a complicated infection is suspected, the patient should be referred to a specialist for computed tomography to assess the severity and extent of disease and identify the underlying causes. The remainder of this chapter focuses on the management of uncomplicated acute bacterial sinusitis. Antibiotics, such as amoxicillin, are recommended to reduce disease duration for patients with acute bacterial sinusitis. Adjuvant, nonantibiotic therapies have a limited role.

NONPHARMACOLOGIC THERAPY

Many symptoms of sinusitis will resolve within 48 hours without medical therapy. When they persist, pharmacotherapy should be

TABLE 117-2 Abbreviated Definitions for Evidence-Based Statements

Statement	Definition
Strong recommendation	The benefits of the recommended approach clearly exceed the risks
Recommendation	The benefits exceed the risks
Option	Either the quality of evidence that exists is suspect, or well-done studies show little clear advantage of one approach over another
No recommendation	Both a lack of pertinent evidence and an unclear balance between benefits and harms

From Rosenfeld RM, Andes D, Bhattacharyya N, et al. Clinical practice guideline: Adult sinusitis. Otolaryngol Head Neck Surg 2007;137(3 Suppl):S1–S31.

TABLE 117-3 Abbreviated Guideline Statements for Acute Bacterial Sinusitis

Practice	Evidence-Based Statement
Consider a sinusitis infection to be of bacterial origin if symptoms persist 10 days or more or if symptoms worsen within 10 days after initial improvement	Strong recommendation
Do not obtain radiographic imaging for patients who meet diagnostic criteria for acute bacterial sinusitis unless a complication or alternative diagnosis is suspected	Recommendation against
Management of acute bacterial sinusitis should include pain assessment and severity-based treatment	Strong recommendation
Clinicians may prescribe therapies for symptomatic relief in acute bacterial sinusitis	Option
Delayed therapy is an option in selected patients with uncomplicated acute bacterial sinusitis who have mild pain, temperature <31°C (101°F), and assurance of follow-up	Option
Amoxicillin should be used as first-line therapy for most adults	Recommendation
If the patient fails therapy, or if the disease worsens with the initial management option by 7 days after diagnosis, then reassess, detect complications, and initiate alternative antibiotic therapy	Recommendation

Adapted from Rosenfeld RM, Andes D, Bhattacharyya N, et al. Clinical practice guideline: Adult sinusitis. Otolaryngol Head Neck Surg 2007;137(3 Suppl):S1–S31.

directed toward symptomatic relief, restoring and improving sinus function, and eradicating the causative pathogen.

Data regarding supportive therapy are limited, but such therapy may be useful in reducing symptoms in some patients.[34] Nasal decongestant sprays that reduce inflammation by vasoconstriction, such as phenylephrine and oxymetazoline, are used often in sinusitis.[30] Use should be limited to no more than 3 days to prevent the development of tolerance and/or rebound congestion. Oral decongestants also may aid in nasal/sinus patency. Irrigation of the nasal cavity with saline and steam inhalation may be used to increase mucosal moisture, and mucolytics (e.g., guaifenesin) may be used to decrease the viscosity of nasal secretions.[30]

Antihistamines should not be used for acute bacterial sinusitis due to of their anticholinergic effects that can dry mucosa and disturb clearance of mucosal secretions.[35] Second-generation antihistamines may play a role in chronic sinusitis, which is frequently accompanied by concomitant allergic rhinitis. Glucocorticoids intranasally may decrease inflammation causing headache, nasal congestion, and facial pain;[39] however, there are limited data to support their use in acute sinusitis.[40]

CLINICAL CONTROVERSY

Proponents of intranasal corticosteroids have suggested that they may alleviate symptoms and hasten recovery due to their local antiinflammatory properties. A systematic review of four studies with 1,943 participants found that patients receiving intranasal corticosteroids were more likely to have symptom resolution or improvement in symptoms than those patients receiving placebo.[40] Furthermore, there appeared to be a dose–response relationship with higher doses of intranasal corticosteroids resulting in a stronger effect. There were no significant differences in adverse effects, drop-outs, or recurrence rates between participants who received intranasal corticosteroids and those who received placebo. This systematic review supports the use of intranasal corticosteroids as monotherapy or adjuvant therapy to antibiotics for the treatment of acute bacterial sinusitis.[40]

PHARMACOLOGIC THERAPY

Several sets of clinical practice guidelines and thought papers have been published in the last few years, and more are in development by professional societies, including the Infectious Diseases Society of America. These include statements from the AAP;[35] the Sinus and Allergy Health Partnership,[33] the American Academy of Otolaryngology–Head and Neck Surgery (AAO-HNS);[37,38] the Agency for Healthcare Research and Quality (AHRQ);[41] and the Joint Task Force on Practice Parameters, representing the American Academy of Allergy, Asthma, and Immunology, the American College of Allergy, Asthma, and Immunology, and the Joint Council of Allergy, Asthma, and Immunology.[42] In addition, there have been several high-quality reviews.[30,31,43,44]

4 Amoxicillin is first-line treatment for acute bacterial sinusitis (Table 117–4). The advantages of amoxicillin include proven efficacy and safety, a relatively narrow antibacterial spectrum, and good tolerability. It is cost-effective in acute uncomplicated disease, and systematic reviews have failed to demonstrate the superiority of alternative antibiotic therapies as compared with amoxicillin.[41,45] High-dose amoxicillin is recommended in situations with a high risk of penicillin-resistant *S. pneumoniae*. See Table 117–5 for dosing guidelines.

If the patient has a penicillin allergy, but it is not a type I, immunoglobulin (Ig) E–mediated reaction (e.g., hives or anaphylaxis), a second-generation cephalosporin is initially recommended

TABLE 117-4 Acute Bacterial Sinusitis Antibiotic Recommendations[a,b]

	Uncomplicated	Treatment Failure or Prior Antibiotic Therapy in Past 4 to 6 Weeks	High Suspicion of Penicillin-resistant *Streptococcus pneumoniae*
First line	Amoxicillin	Amoxicillin-clavulanate (high-dose) or cephalosporin	Amoxicillin (high-dose) or clindamycin
Second line	–	Respiratory fluoroquinolone	Respiratory fluoroquinolone
Non–type 1 allergy	Cephalosporin	Cephalosporin	Clindamycin or respiratory fluoroquinolone
Type 1 allergy	Clarithromycin, azithromycin, trimethoprim-sulfamethoxazole, doxycycline, or a respiratory fluoroquinolone	Respiratory fluoroquinolone	Clindamycin or respiratory fluoroquinolone

[a] See Table 117–5 for dosing guidelines in children and adults.

TABLE 117-5 Oral Dosing Guidelines for Acute Bacterial Sinusitis

Medication	Adult Dosage	Pediatric Dosage
Amoxicillin	Low dose: 500 mg three times daily High dose: 2 g twice daily	Low dose: 45 mg/kg/day divided in three doses High dose: 90 mg/kg/day divided in two doses
Amoxicillin-clavulanate	Low dose: 500/125 mg three times daily High dose: 2 g/125 mg twice daily	Low dose: 45 mg/kg/day of amoxicillin and 3.2 mg/kg/day of clavulanate divided in three doses High dose: 90 mg/kg/day of amoxicillin and 6.4 mg/kg/day of clavulanate divided in two doses
Cefuroxime	250–500 mg twice daily	15 mg/kg/day divided in two doses
Cefaclor	250–500 mg three times daily	20 mg/kg/day divided in three doses
Cefixime	200–400 mg twice daily	8 mg/kg/day in one dose or divided in two doses
Cefdinir	600 mg daily or divided in two doses	14 mg/kg/day in one dose or divided in two doses
Cefpodoxime	200 mg twice daily	10 mg/kg/day in two divided doses (maximum 400 mg daily)
Cefprozil	250–500 mg twice daily	15–30 mg/kg/day divided in two doses
Doxycycline	100 mg every 12 hours	–
Trimethoprim-sulfamethoxazole	160/800 mg every 12 hours	6–8 mg/kg/day trimethoprim, 30–40 mg/kg/day sulfamethoxazole divided in two doses
Clindamycin	150–450 mg every 6 hours	30–40 mg/kg/day divided in three doses
Clarithromycin	250–500 mg twice daily	15 mg/kg/day divided in two doses
Azithromycin	500 mg day 1, then 250 mg/day × days 2–5	10 mg/kg day 1, then 5 mg/kg/day × days 2–5
Levofloxacin	500 mg daily	–

From Piccirillo JF. Clinical practice: Acute bacterial sinusitis. N Engl J Med 2004;351(9):902–910; Scheid DC, Hamm RM. Acute bacterial rhinosinusitis in adults: 2. Treatment. Am Fam Physician 2004;70(9):1697–1704; and Subcommittee on Management of Sinusitis and Committee on Quality Improvement. Clinical practice guideline: Management of sinusitis. Pediatrics 2001;108(3):798–808.

(e.g., cefprozil, cefuroxime, or cefpodoxime).[35,46] Patients with type I IgE-mediated reactions to penicillin may be treated with trimethoprim-sulfamethoxazole, doxycycline, azithromycin, or clarithromycin. There is concern, however, regarding increasing resistance to trimethoprim-sulfamethoxazole and macrolides,[33] as well as the high failure rate of all these antibiotics. Respiratory fluoroquinolones may also be suitable alternatives in penicillin-allergic patients.

In the case of treatment failure with amoxicillin (i.e., no improvement in symptoms 72 hours after starting therapy) or in patients who have received antibiotic therapy in the prior 4 to 6 weeks, limitations of initial treatment coverage must be considered.[33] Improved coverage of *H. influenzae* and *M. catarrhalis* with either high-dose amoxicillin plus clavulanate or a β-lactamase-stable cephalosporin that covers *S. pneumoniae* (e.g., cefprozil, cefuroxime, or cefpodoxime) is an option.[33,35] Other alternatives are cefdinir, azithromycin, clarithromycin, and trimethoprim-sulfamethoxazole.[34,35] Clinical cure rates are similar among antibiotics,[47] although local-area resistance rates also must be considered, as well as increasing resistance of *S. pneumoniae, H. influenzae,* and *M. catarrhalis* to trimethoprim-sulfamethoxazole, and of *S. pneumoniae* to macrolides. Respiratory fluoroquinolones and ceftriaxone have also been recommended.

If drug-resistant *S. pneumoniae* is suspected (daycare attendance, recent antibiotic use, age younger than 2 years), then high-dose amoxicillin should be given. Some recommend clindamycin, but it is important to note that this drug is not active against *H. influenzae* and *M. catarrhalis*.[35] In adults, respiratory fluoroquinolones are considered to be second line in patients who have failed other therapies, have recently received other antibiotics, or in whom there is a high suspicion for drug-resistant *S. pneumoniae*.[33]

The duration of therapy for treatment of sinusitis is not well established. Most trials have used 10- to 14-day antibiotic courses for uncomplicated sinusitis.[45] A 3-day course of azithromycin was approved for use in sinusitis in both Canada and the United States. A randomized, double-blind study demonstrated that azithromycin 500 mg daily for 3 or 5 days was as effective as amoxicillin-clavulanate over 10 days.[46] Furthermore, an extended-release single-dose preparation of azithromycin approved in the United States. However, data supporting these short regimens are limited, and new guidelines express concern over macrolide-resistant *S. pneumoniae*.[33] The current recommendations are 10 to 14 days of antibiotic therapy or at least 7 days after signs and symptoms are under control.[30,33,43]

PHARMACOECONOMIC CONSIDERATIONS

Similar to acute otitis media, pharmacoeconomic considerations in acute bacterial sinusitis are minimal, as the empiric antibiotic of choice is generically available, and meta-analyses have failed to demonstrate superior efficacy with more costly therapies.[41,45] More expensive therapies may be justified if drug-resistant pathogens are suspected or documented.

EVALUATION OF THERAPEUTIC OUTCOMES

Persistent or worsening symptoms 72 hours after initiating antibiotic therapy should be considered treatment failure.[30,33,43] Referral to a specialist should be considered for patients who have not responded to first- or second-line therapy; for those with severe, recurrent, and chronic disease; and for patients who are at risk for complications. Patients who experience changes in visual acuity or mental status should be referred immediately. Surgery may be considered in more complicated patients. Acute bacterial sinusitis lasts less than 30 days with complete resolution of symptoms, whereas chronic sinusitis is defined as episodes of inflammation lasting more than 3 months with persistence of respiratory symptoms.[30,35]

ACUTE PHARYNGITIS

1 2 Pharyngitis is an acute infection of the oropharynx or nasopharynx.[48] It is responsible for 1% to 2% of all outpatient visits.[49] Although viral causes are most common, group A β-hemolytic streptococci (GABHS; also known as *S. pyogenes*), is the primary bacterial cause.[48,50] GABHS is commonly known as "strep throat."

EPIDEMIOLOGY

Acute pharyngitis accounts for ~2 million emergency department and outpatient department visits per year,[51] at a cost of approximately $1.2 billion total and up to $539 million for children alone.[52] Although viral causes are most common, GABHS is the primary bacterial cause and is associated with rare but severe sequelae if not treated appropriately.[48,50] Nonsuppurative

complications such as acute rheumatic fever, acute glomerulonephritis, and reactive arthritis may occur, as well as suppurative complications, such as peritonsillar abscess, retropharyngeal abscess, cervical lymphadenitis, mastoiditis, otitis media, sinusitis, and necrotizing fasciitis.

Although all age groups are susceptible, epidemiologic data demonstrate certain groups are at higher risk. Children ages 5 to 15 years are most susceptible; parents of school-age children and those who work with children are also at increased risk. Pharyngitis in a child younger than 3 years of age is rarely caused by GABHS.[48,50]

Seasonal outbreaks occur, and the incidence of GABHS is highest in winter and early spring.[48,53] The incubation period is 2 to 5 days, and the illness often occurs in clusters.[53,54] Spread occurs via direct contact (usually from hands) with droplets of saliva or nasal secretions, and transmission is thus worse in institutions, schools, families, and areas of crowding.[54,55] Untreated, patients with streptococcal pharyngitis are infectious during the acute illness and for another week thereafter.[56] Effective antibiotic therapy reduces the infectious period to about 24 hours.

Acute rheumatic fever is rarely seen in developed countries. In the United States, acute rheumatic fever secondary to GABHS infection was a cause of concern in the 1950s and was the major reason for penicillin therapy, but the annual incidence of this disease today is extremely rare (≤1 case per 1 million population). However, some risk does remain; outbreaks have been reported in the United States as recently as the late 1980s and early 1990s. Furthermore, acute rheumatic fever is widespread in developing countries.[57] South Central Asia's median incidence of acute rheumatic fever is 54 cases per 100,000 compared with 10 cases per 100,000 in established markets.[57]

ETIOLOGY

Viruses cause the majority of acute pharyngitis cases. Specific etiologies include rhinovirus (20%), coronavirus (<5%), adenovirus (5%), herpes simplex virus (4%), influenza virus (2%), parainfluenza virus (2%), and Epstein-Barr virus (<1%).[48,50] A bacterial etiology is far less likely. Of all the bacterial causes, GABHS is the most common (10–30% of persons of all ages with pharyngitis) and is the only commonly occurring form of acute pharyngitis for which antibiotic therapy is indicated.[48] In the pediatric population, GABHS causes 15% to 30% of pharyngitis cases. In adults, GABHS is responsible for 5% to 15% of all symptomatic episodes of pharyngitis.[48–50,54]

Other, less-common causes of acute pharyngitis are groups C and G *Streptococcus, Corynebacterium diphtheriae, Neisseria gonorrhoeae, Mycoplasma pneumoniae, Arcanobacterium haemolyticum, Yersinia enterocolitica,* and *Chlamydia pneumoniae.* Treatment options for these organisms are not addressed in this chapter.[48,50]

PATHOPHYSIOLOGY

The mechanism by which GABHS causes pharyngitis is not well defined. Asymptomatic pharyngeal carriers of the organism may have an alteration in host immunity (e.g., a breach in the pharyngeal mucosa) and the bacteria of the oropharynx, allowing colonization to become an infection. Pathogenic factors associated with the organism itself may also play a role. These include pyrogenic toxins, hemolysins, streptokinase, and proteinase.

CLINICAL PRESENTATION

The most common symptom of pharyngitis is sore throat. Accurate differentiation of GABHS from pharyngitis caused by other agents is key for treatment decisions; however, this can be difficult even for experienced clinicians. Therefore, incorporation of microbiologic testing is recommended if the patient meets the appropriate clinical criteria.

TABLE 117-6 Modified Centor Criteria for Clinical Prediction of Group A β-Hemolytic Streptococcal Pharyngitis[a]

Criteria	Points
Temperature >38°C (101°F)	1
Absence of cough	1
Swollen, tender anterior cervical nodes	1
Tonsillar swelling or exudate	1
Age	
3–14 years	1
15–44 years	0
45 years or older	−1

Score	Risk of streptococcal infection
≤0	1%–2.5%
1	5%–10%
2	11%–17%
3	28%–35%
≥4	51%–53%

[a]The original Centor score applies to adults only. This modified version allows for age.
From McIsaac WJ, Kellner JD, Aufricht P, et al. Empirical validation of guidelines for the management of pharyngitis in children and adults. JAMA 2004;291(13):1587–1595.

Clinical scoring systems such as the Centor criteria,[58] or modifications of the Centor criteria,[59] have been advocated for clinical diagnosis in adults as a way to overcome the lack of sensitivity and specificity of clinician judgment and to avoid laboratory testing of all patients.[49,54] Table 117–6 lists the modified Centor criteria. The modified Centor criteria include age as a factor for scoring. Concern exists that use of these criteria alone leads to overprescribing.[48,50,60] Guidelines from the American Heart Association (AHA), which are endorsed by the AAP, suggest that testing be done in all patients with signs and symptoms of streptococcal pharyngitis. Only those with a positive test for GABHS require antibiotic treatment.[48,53,60] Limiting testing to patients who meet two or more Centor criteria will minimize overtesting.[59,60] The simplest approach is likely point-of-care testing with culture confirmation in cases of negative results. This ensures those with the condition are not undertreated. Table 117–7 compares recommendations for diagnostic testing and antibiotic treatment among recent GABHS pharyngitis guidelines.

Laboratory testing should not be used without consideration of clinical criteria. This is because a positive test does not necessarily indicate disease. A positive test may indicate the patient is a carrier for GABHS (not active infection), and the cause of pharyngitis could be viral. Approximately 5% to 20% of children are carriers; the prevalence is lower among adults.[53] Table 117–8 lists the evidence-based principles for diagnosis of GABHS. There are several options to test for GABHS. A throat swab can be sent for culture or used for the rapid antigen-detection test (RADT). Cultures are the gold standard, but they require 24 to 48 hours for results.[50] The RADT is more practical in that it provides results quickly, it can be performed at the bedside, and it is less expensive than culture. If RADT yields negative test results, it is generally recommended to follow up with a throat culture to confirm results. Cultures are recommended for children and adolescents who have a negative RADT.[48] However, the AHA, which is the most recent position statement, recommends follow-up throat cultures for all patients after a negative RADT.[61] Delaying therapy while awaiting culture results does not affect the risk of complications (although some argue that symptomatic benefit is postponed, and contagion remains), and patients must be educated as to the value of waiting, given the low false-negative rate of RADT.[62]

TABLE 117-7 Recommendations for Diagnostic Testing and Indications for Antibiotic Treatment in Suspected Group A β-hemolytic Streptococcal Pharyngitis[a]

Guideline	Population		Tests	Antibiotic Treatment
ACP-ASIM, AAFP, CDC[54]	Suspected pharyngitis evaluated using Centor criteria	0 or 1 criteria	None	No treatment
		2 or 3 criteria	RADT	Yes, if test positive
		3 or 4 criteria	None	Yes (empiric) Negative RADT with sensitivity > 80% does not need follow-up throat culture
IDSA[48]	Suspected pharyngitis with clinical and epidemiologic factors suggestive of GABHS pharyngitis[b]		RADT or throat culture	Yes, if test positive Negative RADT results must be confirmed with throat culture for children and adolescents only
AHA[a61]	Suspected pharyngitis with clinical and epidemiologic factors suggestive of GABHS pharyngitis[b]		RADT or throat culture	Yes, if test positive Negative RADT results must be confirmed with throat culture for all patients tested

[a]The American Academy of Pediatrics endorses the American Heart Association statement.[61]
[b]Epidemiologic factors suggestive of GABHS pharyngitis include history of exposure, presentation in winter or early spring, and patient age 5 to 15 years.

CLINICAL PRESENTATION AND DIAGNOSIS OF GROUP A STREPTOCOCCAL PHARYNGITIS

General

- A sore throat of sudden onset that is mostly self-limited
- Fever and constitutional symptoms resolving in about 3 to 5 days
- Clinical signs and symptoms are similar for viral causes and nonstreptococcal bacterial causes

Signs and Symptoms

- Sore throat
- Pain on swallowing
- Fever
- Headache, nausea, vomiting, and abdominal pain (especially children)
- Erythema/inflammation of the tonsils and pharynx with or without patchy exudates
- Enlarged, tender lymph nodes
- Red swollen uvula, petechiae on the soft palate, and a scarlatiniform rash
- Several symptoms that are not suggestive of group A streptococci are cough, conjunctivitis, coryza, and diarrhea

Signs Suggestive of Viral Origin for Pharyngitis

- Conjunctivitis
- Coryza
- Cough
- Diarrhea

Laboratory Tests

- Throat swab and culture
- Rapid antigen detection testing (RADT)

TREATMENT

DESIRED OUTCOME

The goals of treatment for pharyngitis are to improve clinical signs and symptoms, minimize adverse drug reactions, prevent transmission to close contacts, and prevent acute rheumatic fever and suppurative complications, such as peritonsillar abscess, cervical lymphadenitis, and mastoiditis.[48,49]

GENERAL APPROACH TO TREATMENT

Once the diagnosis of GABHS pharyngitis has been made, the clinician must decide appropriate supportive care, when to initiate antibiotic therapy, the appropriate antibiotic, and the duration of therapy. The selection of appropriate antibiotic therapy will involve careful consideration of cost, safety, efficacy, potential for regimen adherence, and bacterial resistance rates. Clinicians should be aware of the local resistance patterns, which may differ from the national patterns.

Antibiotic overuse has been well documented.[48,60] Antibiotic therapy should be reserved for those patients with clinical and epidemiologic features of GABHS pharyngitis, preferably with a positive laboratory test. Empiric therapy is not recommended unless there is a high index of suspicion based on clinical or epidemiologic data and laboratory results are pending. However, it is very important to discontinue empiric antibiotics if laboratory results are negative.

TABLE 117-8 Evidence-Based Principles for Diagnosis of Group A *Streptococcus*

Recommendations	Level
Selective use of diagnostic testing only in those with clinical features suggestive of group A *Streptococcus* will increase the proportion of positive tests as well as results of those truly infected, not carriers.	A-II
Clinical diagnosis cannot be made with certainty even by the most experienced clinician; bacteriologic confirmation is required.	A-II
Throat culture remains the diagnostic standard, with a sensitivity of 90% to 95% for detection of group A *Streptococcus* if done correctly.	A-II
Rapid identification and treatment of patients with disease can reduce transmission, allow patients to return to work or school earlier, and reduce the acute morbidity of the disease.	A-II
The majority of rapid antigen detection tests available have a specificity >95% (minimizes overprescribing to those without disease) and a sensitivity of 80% to 90% compared with culture.	A-II
Early initiation of antibiotic therapy results in faster resolution of signs and symptoms. Delays in therapy (if awaiting cultures) can be made safely for up to 9 days after symptom onset and still prevent major complications such as rheumatic fever.	A-I

Rating:
Strength of recommendation: A to E
Evidence to support use: A, good; B, moderate; C, poor
Evidence against use: D, moderate; E, good
Quality of evidence: I, II, or III
I: At least one randomized controlled trial
II: At least one well-designed clinical trial, not randomized, or a cohort or case-controlled analytical study, or from multiple time series, or from dramatic results of an uncontrolled trial
III: Opinions of respected authorities

NONPHARMACOLOGIC THERAPY

Supportive care should be offered for all patients with acute pharyngitis. In a prospective study of the care of patients with "sore throat," patient satisfaction with their care was strongly associated with whether the physician addressed the patient's concerns rather than antibiotic prescribing.[63] Pharmacologic interventions include antipyretic medications and nonprescription lozenges and sprays containing menthol and topical anesthetics for temporary relief of pain.[50] Because pain is often the primary reason for visiting a physician, emphasis on analgesics such as acetaminophen and NSAIDs to aid in pain relief is strongly recommended.[64] However, acetaminophen is a better option because there is some concern that NSAIDs may increase the risk for necrotizing fasciitis/toxic shock syndrome. Toxic shock syndrome has been linked to GABHS pharyngitis. Symptoms may resolve 1 or 2 days sooner with such interventions.[49,50,54]

PHARMACOLOGIC THERAPY

4 For over 30 years, GABHS isolated in the United States has shown susceptibility to penicillin. Because penicillin has a narrow spectrum of activity and is readily available, safe, and inexpensive, it is considered the treatment of choice.[48,49] The only controlled studies that have demonstrated that antibiotic therapy prevents rheumatic fever following GABHS pharyngitis were done with procaine penicillin, which was later replaced with benzathine penicillin.[65,66] Penicillin given by other routes is assumed to be equally efficacious. The ability of other antibiotics to eradicate GABHS has led to extrapolation that these antibiotics will also prevent rheumatic fever.[54] Amoxicillin can be used in children because the suspension is more palatable than penicillin.[48,55] Gastrointestinal (GI) adverse effects and rash, however, are more common. A once-daily, extended-release formulation of amoxicillin has been approved for treatment of GABHS pharyngitis in adults and children ages 12 years and older; however, use of once-daily dosing in GABHS pharyngitis is controversial.

CLINICAL CONTROVERSY

Once-daily amoxicillin given at a dose of 750 mg is as effective as penicillin 250 mg given three times daily (duration 10 days each) in children ages 4 to 18 years with GABHS pharyngitis.[84] This dosing regimen has not yet been endorsed by expert panels but may gain support in the future if the results are reproducible.[48,49,54]

In penicillin-allergic patients, erythromycin or a first-generation cephalosporin such as cephalexin can be used if the reaction is non-IgE-mediated.[50] Newer macrolides such as azithromycin and clarithromycin are equally effective as erythromycin and cause fewer GI adverse effects. Second-generation cephalosporins, such as cefuroxime and cefprozil, or third-generation cephalosporins, such as cefpodoxime and cefdinir, which are β-lactamase-stable, have been advocated for clinical failures with penicillin. In cases of documented macrolide resistance (owing to low-level macrolide resistance—erythromycin MIC 1 to 8 mcg/mL—because of expression of the *mefA/E* gene leading to efflux of macrolide out of the bacterial cell), clindamycin is an alternative. If patients are unable to take oral medications, intramuscular benzathine penicillin can be given, although it is painful.[48]

There are no definitive trial data to support a particular antibiotic regimen preferentially over another to treat multiple recurring episodes of culture-positive GABHS pharyngitis. Amoxicillin-clavulanate or clindamycin may be considered for recurrent episodes of pharyngitis to maximize bacterial eradication in potential carriers and to counter co-pathogens that produce β-lactamases.[48,53] Surgical removal of tonsils may be indicated in patients whose frequency of episodes does not diminish over time, and there is no other explanation for recurrence.[48] Tables 117–9 and 117–10 outline dosing for acute and recurrent episodes of GABHS pharyngitis.

To date, no resistance of GABHS to penicillin has been reported in clinical isolates.[48,49,53,67,68] Macrolide resistance is low (<5%) and is not widespread.[67–73] There has been a report of an outbreak of macrolide-resistant GABHS pharyngitis in the United States and increasing rates in New York City.[68] Internationally, higher rates have also been reported,[73] and as usage of macrolides increases, these rates will continue to rise. Consequently, use of newer macrolides as first-line therapy is discouraged in febrile patients with upper respiratory tract infections. GABHS resistance rates to tetracyclines and sulfonamides are high; therefore, use of these antibiotics is no longer recommended.[48]

The ideal time to start antibiotic therapy has not been established. The immediate start of antibiotic therapy does not affect the risk of developing rheumatic fever, and no evidence suggests it reduces recurrent infection.[74,75] Clinical guidelines recommend withholding antibiotics unless the patient has a positive laboratory test or three or four of the Centor criteria. Nevertheless, a survey of clinicians treating children and adolescents with acute pharyngitis revealed that 42% of clinicians would start antibiotic therapy before diagnostic results were received and continue antibiotics despite a negative test result.[76]

The impact of appropriate antibiotic therapy is limited to decreasing the duration of signs and symptoms by 1 or 2 days.[49,77] It can decrease the severity of pharyngitis symptoms when initiated within 2 or 3 days of onset in patients with proven GABHS.

TABLE 117-9 Dosing Guidelines for Pharyngitis

Medication	Adult Dosage	Pediatric Dosage	Duration	Rating
Preferred antibiotics				
Penicillin V	250 mg three or four times daily or 500 mg twice daily	50 mg/kg/day divided in three doses	10 days	IB
Penicillin benzathine	1.2 million units intramuscularly	0.6 million units for weight ≤27 kg (50,000 units/kg)	One dose	IB
Penicillin G procaine and benzathine mixture	Not recommended in adolescents and adults	1.2 million units (benzathine 0.9 million units, procaine 0.3 million units)	One dose	
Additional effective antibiotics				
Amoxicillin	500 mg three times daily	40–50 mg/kg/day divided in three doses	10 days	IB
Amoxicillin, extended release	775 mg daily	775 mg daily[b]	10 days	IIaB
Cephalexin[a]	250–500 mg orally four times daily	25–50 mg/kg/day divided in four doses	10 days	IB
Clindamycin[a]	20 mg/kg per day divided into 3 doses (maximum 1.8 g/day)		10 days	IIaB
Azithromycin[a]	12 mg/kg once daily (maximum 500 mg)		5 days	IIaB
Clarithromycin[a]	15 mg/kg per day divided in two doses (maximum 250 mg twice daily)		10 days	IIaB
Erythromycin[a]	Variable depending on formulation	Variable depending on formulation	10 days	IIaB

[a]To be prescribed as an alternative to penicillin in penicillin-allergic patients.
[b]Children ages 12 years and older.
Classification of recommendations:
Class I: Conditions for which there is evidence and/or general agreement that a given procedure or treatment is beneficial, useful, and effective.
Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment.
Class IIa: Weight of evidence/opinion is in favor of usefulness/efficacy.
Class IIb: Usefulness/efficacy is less well established by evidence/opinion.
Class III: Conditions for which there is evidence and/or general agreement that a procedure/treatment is not useful/effective and in some cases may be harmful.
Level of evidence:
Level of evidence A: Data derived from multiple randomized clinical trials or meta-analyses.
Level of evidence B: Data derived from a single randomized trial or nonrandomized studies.
Level of evidence C: Only consensus opinion of experts, cases studies, or standard of care.
From Bisno AL, Gerber MA, Gwaltney JM, Jr., et al. Practice guidelines for the diagnosis and management of group A streptococcal pharyngitis: Infectious Diseases Society of America. Clin Infect Dis 2002;35(2):113–125; Bisno AL. Acute pharyngitis. N Engl J Med 2001;344(3):205–211; American Academy of Pediatrics. Group A streptococcal infections. In: Pickering LK, ed. Red Book 2003: Report of the Committee on Infectious Diseases. 26th ed. Elk Grove Village, IL: American Academy of Pediatrics, 2003:526–536; and Gerber MA, Baltimore RS, Eaton CB, et al. Prevention of rheumatic fever and diagnosis and treatment of acute streptococcal pharyngitis: A scientific statement from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee of the Council on Cardiovascular Disease in the Young, the Interdisciplinary Council on Functional Genomics and Translational Biology, and the Interdisciplinary Council on Quality of Care and Outcomes Research: endorsed by the American Academy of Pediatrics. Circulation 2009;119(11):1541–1551.

Microbiologic eradication will occur in 48 to 72 hours, which aids in decreasing transmission.[49] However, antibiotics may be delayed up to 9 days after diagnosis without affecting the incidence of acute rheumatic fever.[62]

The duration of therapy for GABHS pharyngitis is 10 days to maximize bacterial eradication.[48] Although some clinicians have proposed shorter courses of treatment for pharyngitis, confounding factors from these studies, such as the lack of strict entry criteria or differentiation between new or failed infections, limit the widespread application of short antibiotic courses at this time.[48]

CLINICAL CONTROVERSY

Short-course therapy has been advocated to help overcome compliance issues that lead to bacteriologic failure.[85] A 6-day course of amoxicillin demonstrated promising results;[86] in addition, studies with newer broad-spectrum antibiotics (e.g., azithromycin, cefuroxime, cefprozil, cefdinir, cefixime, and cefpodoxime) have demonstrated durations of 5 days or less to be effective.[87,88] A Cochrane review examining short-course (3–6 days) versus standard-duration (10-day course of penicillin) antibiotic therapy for acute GABHS pharyngitis in children reported no significant difference in early bacteriologic treatment failure or late clinical recurrence.[89] Unfortunately, the overall risk of late bacteriologic treatment failure was worse for short-duration treatment. When low-dose azithromycin (10 mg/kg) regimens were eliminated from the analysis, the overall risk of late bacteriologic treatment failure was not different between short-course and standard-duration therapy. The review noted that shorter-duration treatment resulted in better compliance.

Additionally, newer antibiotics that have been studied in this fashion are more expensive and may be more likely to lead to resistance in light of their broad-spectrum of activity.[50]

Overprescribing is common in acute pharyngitis. Antibiotics are prescribed for 73% of patients who visit their provider with a complaint of "sore throat."[78] This is well above the incidence of GABHS pharyngitis. For those who receive antibiotics, 68% of prescriptions are described as being nonrecommended treatments, for example, extended-spectrum macrolides (e.g., azithromycin or clarithromycin) or fluoroquinolones (e.g., ciprofloxacin, levofloxacin, or moxifloxacin). Factors including cost and resistance should discourage this practice.

Approximately 25% of household contacts of a person with acute GABHS pharyngitis harbor GABHS in their upper respiratory tracts.[48] Routine testing of asymptomatic household contacts of an index patient is not recommended. If tested, it is not necessary to treat these asymptomatic carriers. However, it is difficult to ascertain the cause of symptomatic pharyngitis in carriers of GABHS if they do develop symptoms. In cases of acute pharyngitis in GABHS carriers, a treatment course of appropriate antibiotics is recommended.[61]

Patients with documented histories of rheumatic fever (including cases manifested solely by Sydenham chorea) and those with definite evidence of rheumatic heart disease should receive continuous prophylaxis initiated as soon as the patient is diagnosed and the initial infection has been treated. The duration of secondary prophylaxis is individualized based on patient risk of recurrence of rheumatic fever and/or rheumatic heart disease. Intramuscular benzathine penicillin G every 4 weeks is the recommended regimen for secondary prevention in the United States in most circumstances.[61] Additional options for secondary prophylaxis include oral penicillin V and sulfadiazine. Medication adherence is key to successful secondary prevention with oral antibiotics. Sulfadiazine is an effective antibiotic for the

TABLE 117-10 Antibiotics and Dosing for Recurrent Episodes of Pharyngitis

Drug	Adult Dosage	Pediatric Dosage
Clindamycin	600 mg orally divided in two to four doses	20 mg/kg/day orally in three divided doses (maximum 1.8 g/day)
Amoxicillin-clavulanate	500 mg orally twice daily	40 mg/kg/day orally in three divided doses
Penicillin benzathine	1.2 million units intramuscularly for one dose	0.6 million units intramuscularly for weight <27 kg (50,000 units/kg)
Penicillin benzathine with rifampin	As above	As above
	Rifampin 20 mg/kg/day orally in two divided doses during last 4 days of treatment with penicillin (maximum daily dose 600 mg)	Rifampin dose same as adults

From Bisno AL, Gerber MA, Gwaltney JM, Jr., et al. Practice guidelines for the diagnosis and management of group A streptococcal pharyngitis: Infectious Diseases Society of America. Clin Infect Dis 2002;35(2):113–125.

prevention of infection and is appropriate if the patient is penicillin-allergic. Sulfonamides are not appropriate for treatment of GABHS pharyngitis because they are not effective for eradication of GABHS. If individuals are allergic to penicillin and sulfadiazine, a macrolide is recommended; however, this recommendation is based on expert opinion rather than clinical trial data.[61]

PHARMACOECONOMIC CONSIDERATIONS

Adherence to acute pharyngitis guidelines is difficult for many clinicians.[79] A retrospective analysis of visits to a primary care clinic for acute pharyngitis demonstrated that 66% of providers did not adhere to any of the recommended pharyngitis guidelines.[79]

Pharmacoeconomic studies support the use of guideline-concordant therapies for the reduction of healthcare costs and antibiotic resistance in acute pharyngitis. In one pharmacoeconomic study, the annual expenditures for acute pharyngitis were determined to be $1.2 billion, with antibiotic resistance contributing 36% of these costs in a cost of illness analysis.[52] These figures were based on common prescribing practices, including inappropriate antibiotic prescribing for viral pharyngitis. The authors suggested that adherence to guideline recommendations would decrease costs by ~53%.

EVALUATION OF THERAPEUTIC OUTCOMES

Most pharyngitis cases are self-limited; however, antibiotics hasten resolution when given early for proven cases of GABHS pharyngitis.[48] Generally, fever and other symptoms resolve within 3 or 4 days of onset without antibiotics; however, symptoms will improve 16 hours to 2½ days earlier with antibiotic therapy.[48] Follow-up testing is generally not necessary for index cases or in asymptomatic contacts of the index patient.[48,50,53] However, for patients who remain symptomatic or when symptoms recur despite completion of treatment, posttreatment throat cultures 2 to 7 days after completion of antibiotics should be done.[61]

ABBREVIATIONS

MIC: Minimum inhibitory concentration

MIC_{90}: Minimum inhibitory concentration for 90% of isolates

NSAID: Nonsteroidal antiinflammatory drug

GABHS: Group A β-hemolytic streptococci

RADT: Rapid antigen detection testing

CHAPTER 118

Influenza

JESSICA C. NJOKU AND ELIZABETH D. HERMSEN

KEY CONCEPTS

1. Influenza is a viral illness associated with high mortality and high hospitalization rates among persons younger than age 65 years. The aging of the population is contributing to an increased disease burden in the United States.
2. Seasonal influenza epidemics are the result of viral antigenic drift, which is why the influenza vaccine is changed on a yearly basis. Antigenic drift forms the foundation of the recommendation for annual influenza vaccination.
3. The acquisition of a new hemagglutinin and/or neuraminidase by the influenza virus is called *antigenic shift*, which results in a novel influenza virus that has the potential to cause a pandemic.
4. The primary route of influenza transmission is person-to-person via inhalation of respiratory droplets, and transmission can occur for as long as the infected person is shedding virus from the respiratory tract.
5. Clinical diagnosis of influenza is difficult. Classic signs and symptoms include abrupt onset of fever, muscle pain, headache, malaise, nonproductive cough, sore throat, and rhinitis. These signs and symptoms usually resolve within 1 week of presentation.
6. In the United States, the primary mechanism of influenza prevention is annual vaccination. Vaccination not only prevents influenza illness and influenza-related hospitalizations and deaths, but also may decrease healthcare resource use and the overall cost to society.
7. The trivalent influenza vaccine (TIV) and the live-attenuated influenza vaccine (LAIV) are the two commercially available vaccines for prevention of seasonal influenza. Both vaccines contain influenza A subtypes H3N2 and H1N1 and influenza B virus, which are initially grown in hens' eggs. Monovalent live attenuated and inactivated vaccine formulations against novel influenza A H1N1 were distributed during the 2009–2010 season to combat the pandemic. For the 2010–2011 influenza season, the novel H1N1 virus is incorporated within the usual seasonal influenza vaccine.
8. Antiviral drugs for prophylaxis of influenza should be considered adjuncts to vaccine and are not replacements for annual vaccination.
9. The sooner the antivirals are started after the onset of illness, the more effective they are.
10. Oseltamivir and zanamivir are neuraminidase inhibitors that have activity against both influenza A and influenza B viruses, while the adamantanes have activity against only some influenza A H1N1 viruses. Anti-influenza agents are most effective if started within 48 hours of the onset of illness.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

Influenza causes significant morbidity and mortality, particularly among young children and the elderly. Seasonal influenza epidemics result in 25 to 50 million influenza cases, approximately 200,000 hospitalizations, and more than 30,000 deaths each year in the United States. Globally, influenza causes nearly 500,000 deaths each year. Overall, more people die of influenza than of any other vaccine-preventable illness. Significant societal consequences associated with influenza include visits to physicians' offices and emergency departments and days lost from school and/or work. The societal costs associated with influenza are more than $37 billion in the United States alone.[1]

Vaccination is the primary mechanism of prevention of influenza in the United States. The antiviral armamentarium for treatment and prophylaxis of influenza is limited, which further emphasizes the importance of prevention with vaccination and appropriate use of infection control measures during outbreaks. Research toward the development of novel antivirals and vaccines is needed for effective control of seasonal epidemics and for pandemic preparedness.

ETIOLOGY AND EPIDEMIOLOGY

Influenza infection can occur at any time during the year with the highest rates of influenza-associated illness during the winter months. The highest rate of infection occurs in children, but the highest rates of severe illness, hospitalization, and death occur among those older than age 65 years, young children (<2 years old), and those who have underlying medical conditions, including pregnancy and cardiopulmonary disorders, that increase their risk of complications from influenza. 1 The seasonal influenza epidemics from 1979 through 2000 resulted in an average of 226,000 hospitalizations per year with more than 63% of the hospitalizations occurring in those older than age 65 years.[2] More than 90% of seasonal influenza-related deaths occur in those older than age 65 years.[3] Thus the aging of the population is contributing to an

increased disease burden. Deaths associated with influenza often result from secondary bacterial pneumonia, primary viral pneumonia, and/or exacerbation of underlying comorbidities.

INFLUENZA VIRUSES A, B, AND C

Influenza virus types A, B, and C are members of the Orthomyxoviridae family and affect many species, including humans, pigs, horses, and birds. Influenza A and B viruses are the two types that cause disease in humans. Influenza A viruses are responsible for the regular, seasonal epidemics of the flu, whereas influenza B viruses are typically associated with sporadic outbreaks, particularly among residents of long-term care facilities. Influenza A viruses are further categorized into different subtypes based on changes in two surface antigens—hemagglutinin and neuraminidase. Influenza B viruses are not categorized into subtypes.

Hemagglutinin allows the influenza virus to enter host cells by attaching to sialic acid receptors and is the major antigen to which antibodies are directed upon exposure.[5] Neuraminidase allows the release of new viral particles from host cells by catalyzing the cleavage of linkages to sialic acid.[4]

Sixteen hemagglutinin subtypes (H1–H16) and nine neuraminidase subtypes (N1–N9) of influenza A have been isolated from birds. However, the only influenza A subtypes that have circulated among humans since the 1918 pandemic (see Pandemics and Antigenic Shift below) are H1 to H3 and N1 and N2.[4] The primary subtypes of influenza A that have been circulating among humans for the last three decades are H3N2 and H1N1.

ANTIGENIC DRIFT AND ANTIGENIC SHIFT

(2) Immunity to influenza virus occurs as a result of the development of antibody directed at the surface antigens, particularly hemagglutinin. However, immunity to one influenza subtype does not offer protection against other subtypes or types of influenza. Moreover, immunity to one antigenic variant of a subtype of influenza may not confer protection against other antigenic variants. Antigenic variants are created by point mutations in the surface antigens of a particular subtype, resulting in small changes in the hemagglutinin and/or neuraminidase molecules, which is called *antigenic drift*. Antigenic drift is the basis for seasonal epidemics of influenza, the reason for changes in the annual influenza vaccine, and the rationale behind the recommendation for annual vaccination.

Immunity to one subtype of influenza does not confer protection against other subtypes or types. (3) Antigenic shift occurs when the influenza virus acquires a new hemagglutinin and/or neuraminidase via genetic reassortment rather than point mutations.[4] Most likely, the genetic reassortment occurs when an animal that supports the growth of multiple subtypes of influenza, such as a pig, is concurrently infected with two subtypes of the influenza virus. Conversely, antigenic shift may occur directly from avian strains that have gained competency in the human host. Antigenic shift results in the emergence of a novel influenza virus and carries the potential of causing a pandemic. However, novelty alone is insufficient to cause an influenza pandemic; the virus must be able to replicate in humans, spread person-to-person, and affect a susceptible population.[4]

Spanish Influenza of 1918

The influenza pandemic of 1918 was the most significant infectious disease outbreak known to man, causing approximately 40 to 50 million deaths in a year, with more than 500,000 deaths occurring in the United States.[4–6] Although the reports of the first illnesses associated with this pandemic occurred in Spain, there is no evidence that the virus associated with this pandemic actually originated there, indicating a misnomer. The pandemic occurred almost concurrently in Europe, Asia, and North America.[5]

The 1918 pandemic was caused by a particularly virulent influenza A H1N1 virus, which was entirely of avian origin.[7] In contrast to the other pandemics of the 20th century, the 1918 pandemic resulted in an unusual mortality pattern. The mortality peaked for those younger than age 4 years, those between the ages of 25 and 35 years, and those older than 65 years of age, which resulted in a W-shaped mortality curve, as opposed to the U- or J-shaped curve typically associated with influenza.[6] Over half of the deaths occurred in persons ages 20 to 40 years. The death toll associated with this pandemic culminated in an almost 10-year drop in the life expectancy of the population at the time.[6]

Asian Influenza of 1957

The Asian flu pandemic began when a new H2 subtype of influenza A surfaced in Hunan province in China in 1957.[8] The virus appears to have formed from coinfection with an avian H2N2 virus and a human H1N1 virus in a common host, possibly a pig or a human.[9] The H2N2 virus quickly spread to Japan, South America, the United States, New Zealand, and Europe, resulting in approximately 4 million deaths worldwide, with 70,000 deaths occurring in the United States.[5,6,8] Unlike the Spanish flu of 1918, the mortality curve for the Asian flu pandemic was U- or J-shaped, with infants and elderly being most affected.[5]

Hong Kong Influenza of 1968

The H2N2 virus of the Asian flu circulated in the human population until 1968, when a new H3 subtype emerged in China and Hong Kong[8] following genetic reassortment with the H2N2 virus.[5,8] The H3N2 virus quickly spread to the United States and later to Europe. This pandemic caused more than 30,000 deaths in the United States and approximately 2 million deaths worldwide.[5,6,8] The lower morbidity and mortality associated with the Hong Kong flu may be explained by previous exposure of the population to the N2 subtype.[10] Similar to the Asian flu of 1957, the mortality curve for the Hong Kong flu pandemic was U- or J-shaped, primarily affecting infants and elderly.

Avian Influenza

Influenza viruses are in circulation in southern China during all months of the year.[4] Given this fact and the close proximity of dense populations of people, pigs, and wild and domestic birds, this area proves ideal for the development of new influenza viruses via genetic reassortment (antigenic shift), as demonstrated by the pandemics of 1957 and 1968 and, most recently, the emergence of what is known as avian influenza.[4]

The first report of human infection with the avian H5N1 virus occurred in 1997 in Hong Kong in a 3-year-old who had a direct link with chickens and later died.[11] This was followed by 18 confirmed cases and 6 deaths.[12] The virus reemerged in 2003 as an antigenically and genetically different virus that has spread widely through wild and domestic bird populations in Asia, Africa, and Europe as well as infecting humans in 15 countries: Azerbaijan, Bangladesh, Cambodia, China, Djibouti, Egypt, Indonesia, Iraq, Lao People's Democratic Republic, Myanmar, Nigeria, Pakistan, Thailand, Turkey, and Vietnam.[5,13] As of August 21, 2010, 504 cases and 229 deaths caused by H5N1 infection have been reported.[13] The current overall case fatality is 45.4%.

In contrast to the animal-to-human transmission of the 1997 epidemic, occasional human-to-human transmission has been suggested during the outbreaks associated with the H5N1 virus,[14,15] although no cases of transmission via aerosolization have been identified.[16] Clinical presentation includes high fever and influenza-like illness, and watery diarrhea without blood may occur up to

1 week prior to respiratory symptoms.[16] Almost all patients have clinically apparent pneumonia. Progression to death, most commonly as a consequence of respiratory failure, occurs a mean of 9 to 10 days after the onset of illness.[16] The neuraminidase inhibitors, oseltamivir and zanamivir, have activity against the H5N1 virus, although higher doses may be needed. Oseltamivir resistance has been detected in several patients infected with the H5N1 virus who were treated with oseltamivir.[16] Amantadine and rimantadine are ineffective against H5N1. An inactivated monovalent influenza virus vaccine against H5N1 is currently available for vaccination of persons 18 through 64 years of age at increased risk of exposure to the H5N1 influenza virus. Two 1-mL doses given intramuscularly at least 28 days apart (range, 21–35 days) are recommended. The vaccine is supplied in a 5-mL multidose vial, with ~50 mcg thimerosal per dose added as a preservative.[17]

The potential for H5N1 to cause a pandemic is of concern as it could spread more quickly than pandemics of the past because of the mobility of people in today's world. International travel has increased 73% since 1990, with 763 million people crossing international borders in 2004.[18] A severe pandemic, like that of 1918, could cause more than 9 million hospitalizations and more than 1.9 million deaths, whereas a moderate pandemic, like those of 1957 and 1968, could result in more than 800,000 hospitalizations and more than 200,000 deaths in the United States alone.[5]

Swine Influenza of 2009

An outbreak of a novel influenza A H1N1 (formerly swine origin influenza virus [SOIV]) was initially detected in Mexico in March 2009 and subsequently in the United States in April 2009 in California and Texas.[19–21] Since that time, the virus has extended throughout North America, Europe, Asia and subsequently worldwide, prompting the World Health Organization (WHO) on June 11, 2009 to declare phase 6, indicating widespread human infection, for the influenza pandemic.[20] Since 1998, triple reassortant swine influenza A (H1) viruses, containing genes from swine, avian, and human lineages, have circulated among swine in the United States.[21] However, the novel influenza A H1N1 virus is unique in that although much of the genome is similar to the triple reassortant swine viruses previously seen in the United States, the genes encoding for neuraminidase (NA) and matrix proteins (M) are most similar to those circulating in the Eurasian swine population. This particular genetic combination has not been seen before.[21]

Several characteristics of the novel influenza A H1N1 outbreak differs compared with a typical seasonal influenza outbreak. Symptomatology associated with the novel influenza include fever (94%), cough (92%), sore throat (66%), diarrhea (25%), and vomiting (25%).[21,22] The majority of novel influenza A H1N1 cases have occurred in otherwise healthy children and young adults including pregnant women, with the highest incidence reported among those aged 5 to 24 years. Among those who were deceased due to novel H1N1 infection, the median age was 37 years and only ~8% of these were among patients aged ≥65 years.[23] As of August 28, 2009, there were 43,771 confirmed cases, 8,843 hospitalizations, and 556 deaths (15 deaths in individuals 0–4 years, 86 deaths in individuals 5–24 years, 235 deaths in adults 25–49 years, 158 deaths in adults 50–64 years, 50 deaths in adults age ≥65, and 12 deaths for which age was not reported).[24]

Pandemic Preparedness

This chapter is not meant to provide an exhaustive review of the biology of influenza or pandemic preparedness. This topic is rapidly changing and interested readers are referred to the following Websites: *www.pandemicflu.gov*, *www.who.int/csr/disease/avian_influenza/en/*, and *www.cdc.gov/h1n1flu*.

A vital component of pandemic preparedness is forethought—plans must be established for how to effectively triage large numbers of ill patients, prioritize and/or ration vaccine and antivirals, and communicate with the public through mass media during a period of severe labor shortage (a result of stress and illness amongst healthcare workers) and supply shortfall (a result of societal and economic disruption).

PATHOGENESIS

4 The route of influenza transmission is person-to-person via inhalation of respiratory droplets, which can occur when an infected person coughs or sneezes.[25] Transmission may also occur if a person touches an object contaminated with respiratory secretions and then touches their mucus membranes. The incubation period for influenza ranges between 1 and 7 days, with an average incubation of 2 days.[22] Transmission can occur for as long as the infected person is shedding virus from the respiratory tract. Adults are considered infectious within one day before until 7 days after onset of illness. Children, especially younger children, might potentially be infectious for longer periods (>10 days).[22,26,27] Viral shedding can persist for weeks to months in severely immunocompromised people.[27]

The pathogenesis of influenza in humans is not well understood. The severity of the infection is determined by the balance between viral replication and the host immune response.[4] Severe illness is likely a result of both a lack of ability of host defense mechanisms to inhibit viral replication and an overproduction of cytokines leading to tissue damage in the host.[28]

CLINICAL PRESENTATION AND DIAGNOSIS OF INFLUENZA

General

- The clinical diagnosis of influenza can be difficult because the presentation is similar to a number of other respiratory illnesses. The sensitivity of clinical diagnosis ranges from 38% for children to 77% for adults and largely depends on the relative prevalence of influenza and other respiratory viruses circulating in a community.[30]
- The clinical course and outcome are affected by age, immunocompetence, viral characteristics, smoking, comorbidities, pregnancy, and the degree of preexisting immunity.
- Complications of influenza may include exacerbation of underlying comorbidities, primary viral pneumonia, secondary bacterial pneumonia or other respiratory illnesses (e.g., sinusitis, bronchitis, otitis), encephalopathy, transverse myelitis, myositis, myocarditis, pericarditis, and Reye syndrome.

Signs and Symptoms

- 5 Classic signs and symptoms of influenza include rapid onset of fever, myalgia, headache, malaise, nonproductive cough, sore throat, and rhinitis.
- Nausea, vomiting, and otitis media are also commonly reported in children.[31]
- Signs and symptoms typically resolve in approximately 3 to 7 days, although cough and malaise may persist for more than 2 weeks.
- Primary viral pneumonia, occurring predominantly in pregnant women and in those with underlying cardiovascular disease, usually begins with fever and dry cough, which

changes to a productive cough of bloody sputum. This rapidly progresses to dyspnea, hypoxemia, and cyanosis with radiologic evidence of bilateral interstitial infiltrates.[32]

- Secondary bacterial pneumonia is usually seen in individuals with underlying pulmonary disorders and presents during the early stages of defervescence from the influenza infection. These patients usually present with fever, productive cough, and radiologic evidence of consolidation.[32]

Laboratory Tests

- Complete blood count and chemistry panels should be obtained to assess the overall status of the patient.
- The gold standard for diagnosis of influenza is viral culture, which can provide information on the specific strain and subtype. Viral culture has a high sensitivity but can take as long as a week to develop, limiting the clinical relevance of the results.
- Tests such as the rapid antigen and point-of-care (POC) tests, direct fluorescence antibody (DFA) test, and the reverse-transcription polymerase chain reaction (RT-PCR) assay may be used for rapid detection of virus.

Other Diagnostic Tests

- Cultures of potential sites of infection should be obtained if co-infection, superinfection, or secondary infection is suspected.
- Chest radiograph should be obtained if pneumonia is suspected.

Rapid Tests

- Rapid tests have allowed for prompt diagnosis and initiation of antiviral therapy and decreased inappropriate use of antibiotics. Rapid antigen or POC tests use enzyme immunoassay (EIA) technology to provide results within 1 hour of specimen collection. Appropriate specimens for collection, in decreasing order of sensitivity, are nasopharyngeal aspirates, nasopharyngeal swabs/washes, and oropharyngeal swabs.[30] POC tests allow for differentiation of influenza viruses A and B, with sensitivity and specificity ranging from 57% to 90% and 65% to 99%, respectively.[30] In general, use of POC tests is contraindicated in those who have had symptoms for longer than 3 days, and results may be confounded following recent immunization with live-attenuated influenza vaccine.[30]
- DFA testing requires more technical expertise and infrastructure than POC tests. The advantages of DFA are increased sensitivity over POC tests and simultaneous detection of other respiratory viruses, such as respiratory syncytial virus and adenovirus.[30] DFA provides results between 1 and 4 hours after specimen collection and may serve as a confirmatory assay for a POC test.
- RT-PCR assay is a nucleic acid amplification test and is the most sensitive, specific, and versatile diagnostic test for influenza.[30] RT-PCR is replacing viral isolation as the reference standard and can determine the type, subtype, and strain of influenza. Results are provided within 4 to 6 hours of specimen collection. A new RT-PCR for detection of novel influenza A H1N1 is available through the CDC.[22]

PREVENTION

The best means to decrease the morbidity and mortality associated with influenza is to prevent infection through vaccination.[23,26] Appropriate infection control measures, such as hand hygiene, basic respiratory etiquette (e.g., cover your cough, throw tissues away), and contact avoidance, are also important in preventing the spread of influenza. Additionally, chemoprophylaxis is useful in certain situations.

VACCINATION

6 The primary means of influenza prevention employed in the United States is annual vaccination. Vaccination can help prevent hospitalization and death among those at high risk, decrease influenza-like illness, decrease visits to physicians' offices and emergency rooms, decrease otitis media in children, and prevent school and/or work absenteeism. Annual vaccination is now recommended for all peasons aged 6 months or older.

Vaccination is also recommended for those who live with and/or care for people who are at high risk, including household contacts and healthcare workers.

The ideal time for all influenza vaccination is during October or November to allow for the development and maintenance of immunity during the peak of the influenza season.[23,26] Table 118–1 lists the vaccination coverage rates and goals for various patient populations.

Seasonal influenza vaccine will not likely provide protection against the novel influenza A (H1N1) due to absence of or low levels of cross reacting antibodies.[23,26] As a result, new monovalent live-attenuated (mLAIV) and inactivated monovalent influenza vaccine (MIV) formulations against the novel H1N1 virus are available (Table 118–2).[29] Simultaneous administration of inactivated vaccines against seasonal and novel influenza A H1N1 is permissible if given at different sites. However, administration of live attenuated vaccine formulations against seasonal and novel H1N1 simultaneously is not recommended.[23] Based on evolving burden of illness, the age distribution and risk groups most affected, and anticipated vaccine supply, novel H1N1 vaccination efforts were targeted toward certain patient groups[23] with more widespread vaccination possible only after vaccine supply was adequate for demand.[22,23]

7 The two vaccines currently available for prevention of seasonal influenza are the trivalent influenza vaccine (TIV) and the live-attenuated influenza vaccine (LAIV). Both vaccines contain two influenza A subtypes (H3N2 and H1N1) and influenza B virus; the specific strains included in the vaccine each year change based on antigenic drift. The viruses used for both vaccines are initially grown in embryonated hens' eggs, which explains the contraindication for vaccination of persons with a severe allergic reaction to eggs.[26] Afluria is contraindicated in patients with hypersensitivity to

TABLE 118-1 Influenza Vaccination Rates and Goals by Patient Population

Patient Population	Vaccination Coverage	Vaccination Coverage National Goal (2000/2010)

neomycin or polymyxin.[29] Novel influenza A H1N1vaccines from 2009 were manufactured via a similar process as the seasonal influenza vaccines but are monovalent. Likewise, novel influenza vaccine is contraindicated if known hypersensitivity to eggs or chicken protein exists.[29] As with every new vaccine, the CDC encourages individuals to use the Vaccine Adverse Event Reporting System to aide in collecting and analyzing adverse events following vaccination with the novel influenza H1N1 monovalent vaccine.[23]

Trivalent Influenza Vaccine

7 TIV is FDA approved for use in people older than 6 months of age, regardless of their immune status. Of note, several commercial products are available and are approved for different age groups (Table 118–3). TIV is administered intramuscularly and is made with killed viruses, meaning it cannot cause signs and symptoms of influenza-like illness (Table 118–4). Age and immune status can affect the efficacy of TIV as can the similarity of the vaccine to the viruses in circulation.

In children between 6 and 24 months of age, a 2-year randomized study of TIV exhibited 89% seroconversion and efficacy of 66% in year 1 and 7% in year 2 versus culture-confirmed influenza.[33] In children between 1 and 15 years of age, the efficacy of TIV was 91.4% and 77.3% against culture-confirmed influenza A H1N1 and H3N2, respectively. Two doses of TIV are important for children under the age of 9 years, supporting the rationale for the recommendation of a booster dose of TIV at least 1 month after the initial dose in children between 6 months and less than 9 years of age (see Table 118–3).[26]

TIV is also effective in adult populations under and older than the age of 65 years. A double-blind, randomized, controlled trial evaluating TIV in healthy adults younger than the age of 65 years demonstrated an efficacy of 50% against serologically confirmed influenza during a season in which the vaccine and the circulating viruses were not well matched and an efficacy of 86% during a season in which the vaccine and the circulating viruses were well matched.[34] These findings were corroborated by a large Cochrane Database System review, which found that TIV had an efficacy of 70% in healthy adults younger than 65 years of age, regardless of virus and vaccine concordance.[35] Vaccination of those younger than 65 years old during seasons when the virus and vaccine are well-matched results in decreased work absenteeism and healthcare resource use.[34,35]

Adults older than the age of 65 years benefit from influenza vaccination, including prevention of complications and decreased risk of influenza-related hospitalization and death. However, people in

TABLE 118-4 Comparison of Trivalent (TIV) and Live-Attenuated Influenza Vaccine (LAIV)

Characteristic	TIV	LAIV
Age groups approved for use	>6 mo	2–49 y
Immune status requirements	Immunocompetent or immunocompromised	Immunocompetent
Viral properties	Inactivated (killed) influenza A (H3N2), A (H1N1), and B viruses	Live-attenuated influenza A (H3N2), A (H1N1), and B viruses
Route of administration	Intramuscular	Intranasal
Immune system response	High serum IgG antibody response	Lower IgG response and high serum IgA mucosal response

this population may not generate a strong antibody response to the vaccine and may remain susceptible to infection. In patients older than the age of 60 years who do not reside in a long-term care facility, TIV efficacy was 58% against influenza illness.[26] Although the efficacy against influenza illness for those living in long-term care facilities is between 30% and 40%, the vaccine is 50% to 60% effective in preventing influenza-related hospitalization or pneumonia and 80% effective in preventing influenza-related death.[26]

The most frequent adverse effect associated with TIV is soreness at the injection site that lasts for less than 48 hours. TIV may cause fever and malaise in those who have not previously been exposed to the viral antigens in the vaccine.[26] Allergic-type reactions (hives, systemic anaphylaxis) rarely occur after influenza vaccination and are likely a result of a reaction to residual egg protein in the vaccine.

The 1976 swine influenza vaccine was linked to a rise in the incidence of Guillain-Barré syndrome (GBS), and this has propagated the belief that TIV may cause GBS.[26] However, there is insufficient evidence to establish causality. Although several studies have failed to establish a relationship between influenza vaccination and increased frequency of GBS, two studies have demonstrated a small but significant increase in GBS following influenza vaccination.[36,37] Therefore, vaccination should be avoided in persons who are not at high risk for influenza complications and who have experienced GBS within 6 weeks of receiving a previous influenza vaccine.[26] The potential benefits of influenza vaccination in terms of prevention of severe illness, hospitalization, and mortality significantly outweigh the risks of GBS, and vaccination is recommended for all groups previously discussed.

The multidose vials and a few of the single-dose preparations of TIV contain trace to small amounts of a preservative, thimerosal, which is a mercury-containing compound (see Table 118–3). Some individuals are concerned about thimerosal exposure, particularly among children, because of the unfounded belief that thimerosal exposure is linked to the development of autism. No scientifically persuasive evidence exists to suggest harm from thimerosal exposure from a vaccine. Conversely, accumulating evidence reports the lack of harm from such exposure.[38–40] Thus, similar to GBS, the potential benefits of influenza vaccination in terms of prevention of severe illness, hospitalization, and mortality significantly outweigh the theoretical risk associated with thimerosal exposure, and vaccination is recommended for all groups previously discussed. However, to maximize the public health benefit and placate concerned individuals, thimerosal-free vaccine is available (see Table 118–3).

Live-Attenuated Influenza Vaccine

7 LAIV is made with live, attenuated viruses and is approved for intranasal administration in healthy people between 2 and 49 years of age (see Table 118–4). Advantages of LAIV include its ease of administration, intranasal rather than intramuscular administration, and the potential induction of broad mucosal and systemic immune response.[26] The mucosal response occurs at the site of viral entry and may prevent infection before viral replication occurs.[41] LAIV is more expensive than TIV and is approved for use in a more limited population.

Controlled studies support the use of LAIV in healthy people between the ages of 2 and 49 years. Although LAIV was previously FDA approved for children who were at least 5 years old, three pivotal trials led the FDA to approve LAIV for children who were at least 2 years old.[42] LAIV recipients aged 2 to 5 years had 52.5% and 54.4% fewer cases of influenza illness against matched and mismatched strains, respectively, as compared with TIV recipients.

Although LAIV is FDA approved for adults younger than the age of 49 years, LAIV is effective in healthy adults between 18 and 64 years old.[43] Vaccination reduced the number of severe febrile illnesses by 18.8% and febrile upper respiratory tract illnesses by 23.6%.[43] Additionally, vaccination led to fewer days of illness, fewer days lost from work, fewer visits to healthcare providers, and decreased use of prescription antibiotics and nonprescription medications.[43]

The adverse effects typically associated with LAIV administration include runny nose, congestion, sore throat, and headache. Because LAIV contains live, attenuated viruses, viral shedding may occur for several days following vaccination with LAIV, although this should not be equated with person-to-person transmission.[26] Additionally, because LAIV contains live-attenuated viruses, which carry a theoretical infection risk, LAIV should not be given to immunosuppressed patients or given by healthcare workers who are severely immunocompromised. Moreover, for the reasons discussed in the TIV section, LAIV should not be administered to persons with a history of GBS or hypersensitivity to eggs.

CLINICAL CONTROVERSY

LAIV is not recommended in several populations, including people older than 50 years and pregnant women, largely because the vaccine has not been studied extensively in these populations. However, many clinicians believe the use of LAIV in these populations is acceptable.

POSTEXPOSURE PROPHYLAXIS

8 Antiviral drugs available for prophylaxis of influenza should be considered adjuncts but are not replacements for annual vaccination. The two classes of antiviral drugs available for influenza prophylaxis are the adamantanes and the neuraminidase inhibitors. Adamantane monotherapy is currently not recommended for prophylaxis or treatment in the United States because of the rapid emergence of resistance.[26,27,49] Both of the neuraminidase inhibitors, oseltamivir and zanamivir, are effective prophylactic agents against influenza in terms of preventing laboratory-confirmed influenza when used for seasonal prophylaxis (67% and 85% effective for zanamivir and oseltamivir, respectively) and preventing influenza illness among persons exposed to a household contact who was diagnosed with influenza (79%–81% and 68%–89% effective for zanamivir and oseltamivir, respectively).[37,44–46] Additionally, oseltamivir was 92% effective against influenza and also reduced associated complications when used as seasonal prophylaxis among immunized, institutionalized, elderly patients.[47] However, recent surveillance data and susceptibility testing have identified strains of influenza A, mainly H1N1, with reduced susceptibility to oseltamivir, resulting in alterations to the recommendations for oseltamivir

TABLE 118-5 Antiviral Susceptibilities of Circulating Viruses

	Oseltamivir	Zanamivir	Adamantanes
Novel influenza A (H1N1) 2009	Susceptible[a]	Susceptible	Resistant
Seasonal A (H1N1)	Mostly resistant	Susceptible	Mostly susceptible
Seasonal A (H3N2)	Susceptible	Susceptible	Resistant
Influenza B	Susceptible	Susceptible	Resistant
Avian influenza (H5N1)	Susceptible	Susceptible	Variable

[a]Small number of isolates shown to be resistant to oseltamivir.
From WHO.[49]

use for influenza treatment and chemoprophylaxis (Tables 118–5 and 118–6).[48,49] Due to the emergence of novel H1N1 influenza, in 2009 dosing recommendations for oseltamivir were expanded by the FDA to include children older than 3 months of age, and zanamivir is approved for prophylaxis in those older than the age of 5 years.[50] Table 118–7 gives dosing recommendations.

In those patients who did not receive the influenza vaccination and are receiving an antiviral drug for prevention of disease during the influenza season, the medication should optimally be taken for the entire duration of influenza activity in the community. The use of prophylaxis requires clinical judgment and depends on a variety of factors, but prophylaxis for seasonal influenza should be considered during influenza season for the following groups of patients:

- Persons at high risk of serious illness and/or complications who cannot be vaccinated
- Persons at high risk of serious illness and/or complications who are vaccinated after influenza activity has begun in their community since the development of sufficient antibody titers after vaccination takes approximately 2 weeks

TABLE 118-6 Interim Recommendations for the Selection of Antiviral Treatment Based on Confirmed Influenza Subtypes

Laboratory Test	Predominant Circulating Virus	Preferred	Alternative
Not performed or negative, but influenza suspected clinically	H1N1 (seasonal or novel) or unknown	Zanamivir	Oseltamivir + rimantadine[a,b]
Not performed or negative, but influenza suspected clinically	H3N2 or B	Oseltamivir or zanamivir	None
Positive novel H1N1	NA	Oseltamivir	Zanamivir
Positive A	H1N1 (seasonal or novel) or unknown	Zanamivir	Oseltamivir + rimantadine[a,b]
Positive A	H3N2 or B	Oseltamivir or Zanamivir	None
Positive B	Any	Oseltamivir or Zanamivir	None
Positive A + B	H1N1 (seasonal or novel) or unknown	Zanamivir	Oseltamivir + rimantadine[a,b]
Positive A + B	H3N2 or B	Oseltamivir or zanamivir	None

[a]Preferred if severely ill.
[b]Amantadine can be substituted for rimantadine but has increased risk of adverse events.
Modified from CDC on olsetamivir resistance[48] *and Harper et al.*[27]

- Unvaccinated persons who have frequent contact with those at high risk
- Persons who may have an inadequate response to vaccination (e.g., advanced HIV disease)
- Long-term care facility residents, regardless of vaccination status, when an outbreak has occurred in the institution
- Unvaccinated household contacts of someone who was diagnosed with influenza

Prophylaxis for novel H1N1 influenza should be considered in the following groups:

- Persons at high risk of serious illness and/or complications who have had close contact with persons with laboratory- or clinically confirmed novel H1N1 infection during that person's infectious period
- Healthcare/public health personnel who have had recognized, unprotected close contact with persons with laboratory- or clinically confirmed novel H1N1 infection during that person's infectious period

LAIV should not be administered until 48 hours after influenza antiviral therapy has stopped, and influenza antiviral drugs should not be administered for 2 weeks after the administration of LAIV because the antiviral drugs inhibit influenza virus replication.[38] No contraindication exists for concomitant use of TIV and influenza antiviral drugs.

SPECIAL POPULATIONS

Pregnant women and immunocompromised hosts are special populations at increased risk of influenza complications and are also populations in whom careful consideration must be given in regard to prevention strategies.

Pregnant Women

Pregnant women, regardless of trimester, should receive annual influenza vaccination with TIV but not with LAIV.[23,26] No studies have demonstrated an increased incidence of adverse effects in mothers or their infants related or potentially related to TIV, but no such data exist for LAIV.[51] TIV is also safe for breastfeeding mothers. No data exist for LAIV and breast-feeding, but caution is warranted because of the potential for viral shedding.[26] The effects of the monovalent vaccines against the novel H1N1 virus on fetal development or reproductive capacity is unknown due to lack of data (pregnancy category C).[23]

Immunocompromised Hosts

Immunocompromised hosts should receive annual influenza vaccination with TIV but not LAIV. TIV was 100% effective against laboratory-confirmed influenza in HIV-positive patients with no significant effect on viral load or CD4 cell count.[52] However, antibody titers may not be as high as in immunocompetent individuals and are not improved with a second dose of vaccine.[53] Similarly, antibody titers may not be as high in solid-organ transplant patients as in immunocompetent persons, but conversely, antibody titers were increased significantly after a second dose of TIV in adult liver transplant patients.[54] Although this suggests a potential benefit from a two-dose regimen, such a regimen is not currently recommended for solid-organ transplant recipients. Data is currently limited in this arena for the novel H1N1 vaccines. However, no contraindication has been noted to date based on preliminary data from clinical trials. Additionally, immune response to vaccine may be less than desired in immunocompromised patients.[23,29]

Large clinical trials evaluating the use of influenza antivirals for prophylaxis are lacking in immunocompromised hosts. Viral

TABLE 118-7 Recommended Daily Dosage of Influenza Antiviral Medications for Treatment and Prophylaxis–United States

Drug	Adult Treatment	Adult Prophylaxis[a]	Pediatric Treatment	Pediatric Prophylaxis
Oseltamivir	75-mg capsule twice daily for 5 days	75-mg capsule daily	≤3 mo[b]: 12 mg twice daily 3–5 mo[b]: 20 mg twice daily 6–11 mo[b]: 25 mg twice daily ≥1 year <15 kg: 30 mg twice daily 16–23 kg: 45 mg twice daily 23–40 kg: 60 mg twice daily >40 kg: 75 mg twice daily All for 5 days	≤3 mo. Not recommended situation judged critical due to limited data in this group 3–5 mo[b]: 20 mg daily 6–11 mo[b]: 25 mg daily ≥1 year ≤15 kg: 30 mg daily 16–23 kg: 45 mg daily 23–40 kg: 60 mg daily >40 kg: 75 mg daily
Zanamivir	2 inhalations twice daily × 5 days	2 inhalations daily	2 inhalations twice daily × 5 days for ≥7 years old	2 inhalations daily for ≥5 years old
Rimantadine[c]	200 mg/day in 1–2 doses × 7 days	200 mg/day in 1–2 doses	1–9 years old or <40 kg: 6.6 mg/kg/day divided twice daily (max 150 mg/day) ≥10 years old: 200 mg/day in 1–2 doses Treat 5–7 days	1–9 years old: 5 mg/kg daily (max 150 mg/day) ≥10 years old: 200 mg/day in 1–2 doses
Amantadine[c]	200 mg/day in 1–2 doses until 24–48 h after symptom resolution	Same as treatment doses	>12 years old: same as adult 1–9 years old: 5 mg/kg/day in 1–2 doses; max 150 mg/day ≥10–12 years old: 100 mg orally twice daily	Same as treatment doses

[a]If influenza vaccine is administered, prophylaxis can generally be stopped 14 days after vaccination for non-institutionalized persons. When prophylaxis is being administered following an exposure, prophylaxis should be continued for 10 days after the last exposure. In persons at high risk for complications from influenza for whom vaccination is contraindicated or expected to be ineffective, chemoprophylaxis should be continued for the duration that influenza viruses are circulating in the community during influenza season.

[b]Emergency use authorization for pandemic H1N1 virus from the CDC.

[c]Monotherapy not recommended due to rapid emergence of resistance when used alone.

Modified from Fiore et al.[26]

shedding occurs for prolonged periods in this population and may promote the development of antiviral resistance, which has already been documented with oseltamivir in HIV-positive patients.[55,56]

TREATMENT

Influenza

When prevention efforts fail or are not used, clinicians must turn to the agents available for treatment of influenza. Currently, the antiviral treatment options are limited, particularly in the face of resistance to the adamantanes and oseltamivir.

CLINICAL CONTROVERSY

Some clinicians debate the cost-benefit of the use of diagnostic tests for influenza as well as treatment of influenza in otherwise healthy individuals who are likely to experience resolution without treatment. This controversy is compounded by the fact that the diagnostic tests and the benefits associated with treatment of influenza are highest early in the disease process, and many patients present after this time period.

GOALS OF THERAPY

The four primary goals of therapy of influenza are as follows:

1. Control symptoms
2. Prevent complications
3. Decrease work and/or school absenteeism
4. Prevent the spread of infection

GENERAL APPROACH TO TREATMENT

In the era of pandemic preparedness and increasing resistance, early and definitive diagnosis of influenza is crucial. 9 The currently available antiviral drugs are most effective if started within 48 hours of the onset of illness. Moreover, the sooner the antiviral drugs are started after the onset of illness, the more effective they are. Antiviral drugs shorten the duration of illness and provide symptom control. Adjunct agents, such as acetaminophen for fever or an antihistamine for rhinitis, may be used concomitantly with the antiviral drugs.

NONPHARMACOLOGIC THERAPY

Patients suffering from influenza should get adequate sleep and maintain a low level of activity. They should stay home from work and/or school in order to rest and prevent the spread of infection. Appropriate fluid intake should be maintained. Cough/throat lozenges, warm tea, or soup may help with symptom control (cough, sore throat).

PHARMACOLOGIC THERAPY

The two classes of antiviral drugs available for treatment of influenza are the same as those available for prophylaxis and include the adamantanes, amantadine and rimantadine, and the neuraminidase inhibitors, oseltamivir and zanamivir. Although adamantanes maintain activity against most seasonal influenza A H1N1 viruses, they are not currently recommended as monotherapy due to rapid emergence of resistance. A limited discussion of these two agents can be found below, but the focus will be on oseltamivir and zanamivir.

Amantadine and Rimantadine

Amantadine and rimantadine are adamantanes that have activity against seasonal influenza A H1N1 only. The adamantanes block the M2 ion channel, which is specific to influenza A viruses, and

inhibit viral uncoating. Rapid emergence of resistance is a problem with these agents because cross-resistance is conferred by a single point mutation, which is why adamanatane monotherapy is not recommended.[26,27,49] Because oseltamivir resistance among seasonal influenza A H1N1 is increasing, the addition of an adamantine to oseltamivir is recommended when this specific subtype is suspected (Table 118–6). However, adamantanes do not have activity against influenza A H3N2 or influenza B viruses, and thus should not be used for infections due to these viruses.

Oseltamivir and Zanamivir

10 Oseltamivir and zanamivir are neuraminidase inhibitors that have activity against both influenza A and influenza B viruses, although resistance to oseltamivir among seasonal influenza A H1N1 is on the rise.[26,27] Without neuraminidase, release of the virus from infected cells is impaired, and thus, viral replication is decreased. When administered within 48 hours of the onset of illness, oseltamivir and zanamivir may reduce the duration of illness by approximately 1 day versus placebo.[26,27] In a pivotal trial, oseltamivir reduced the time to return to normal health in adults by 1.9 days and the time to return to normal activity by 2.8 days.[57] These reductions have a significant effect on not only the quality of life for the patient but also the societal costs associated with influenza. 9 Of note, the benefits of treatment are highly dependent on the timing of the initiation of treatment, with the ideal initiation period being within 12 hours of illness onset.[58]

Oseltamivir treatment in adults and adolescents with documented influenza illness resulted in a 26.7% reduction in overall antibiotic use, a 55% reduction in lower respiratory tract complications (bronchitis, pneumonia), and a 59% reduction in hospitalizations.[59] Zanamivir treatment in adults and adolescents with influenza-like illness resulted in a 28% reduction in antibiotic use and a 40% reduction in lower respiratory tract complications.[60] The data in these studies largely come from healthy individuals rather than those at highest risk for complications associated with influenza. The impact of appropriate treatment in high-risk populations may be even greater than that which has been documented to date.

Oseltamivir is approved for treatment in those older than the age of 1 year, while zanamivir is approved for treatment in those older than the age of 7 years. Given the recent pandemic of novel H1N1 in 2009, the FDA issued an emergency use authorization (EUA) for oseltamivir that expanded its use to children younger than 1 year of age.[50] The recommended doses vary by agent and age (see Table 118–7), and the recommended duration of treatment for both agents is 5 days. As of June 23, 2010, the expanded use of oseltamivir under the EUA expired. Therefore, oseltamivir and zanamivir can only be used for approved indications and populations.

Neuropsychiatric complications consisting of delirium, seizures, hallucinations, and self-injury in pediatric patients (mostly from Japan) have been reported following treatment with oseltamivir.[61] Since influenza itself can be associated with neuropsychiatric manifestations, a causal relationship between oseltamivir and neuropsychiatric effects has not been delineated.[62–64] However, the label for oseltamivir has been updated to include neuropsychiatric events as a precaution,[62] and their occurrence with use of oseltamivir should not be ignored.

Influenza resistance to the neuraminidase inhibitors has been documented but cross-resistance between the neuraminidase inhibitors has not been reported.[26] Surveillance during the 2008 to 2009 influenza season identified oseltamivir resistance among most influenza A H1N1 virus isolates.[24] Antiviral susceptibility testing of circulating viruses confirmed that seasonal influenza A H3N2 maintains susceptibility to oseltamivir and zanamivir, but the seasonal H1N1 strain is generally oseltamivir resistant. This prompted the CDC and Infectious Diseases Society of America to issue an interim recommendation summarized in Table 118–6, regarding the use of antiviral agents for the management of persons with suspected seasonal influenza A virus infection.[48] The burden of surveillance rests on clinicians to identify local patterns of influenza circulation to guide antiviral therapy.

CLINICAL CONTROVERSY

Some debate exists regarding the benefit of antiviral administration >48 hours after onset. While clinicians agree that the most benefit is achieved the earlier the medications are started, some data suggest benefit even beyond 48 hours after onset, albeit more limited.

SPECIAL POPULATIONS

Inadequate data exist regarding the use of antiinfluenza medications in special populations, such as immunocompromised hosts. Furthermore, limited data exist regarding use of influenza antivirals during pregnancy. The adamantanes are embryotoxic and teratogenic in rats, and limited case reports of adverse fetal outcomes following amantadine use in humans have been published. Oseltamivir and zanamivir have been used but lack solid safety clinical data in pregnant women. Pregnancy should not be considered a contraindication to oseltamivir or zanamivir use. Oseltamivir is preferred for treatment of pregnant women because of its systemic activity; however, the drug of choice for chemoprophylaxis is not yet defined. Zanamivir may be preferred because of its limited systemic absorption, but respiratory complications need to be considered, especially in women with underlying respiratory diseases. Both the adamantanes and the neuraminidase inhibitors are excreted in breast milk and should be avoided by mothers who are breastfeeding their infants. More studies are needed in these populations who are at high risk for serious disease and complications from influenza.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should be monitored daily for resolution of signs and symptoms associated with influenza, such as fever, myalgia, headache, malaise, nonproductive cough, sore throat, and rhinitis. These signs and symptoms will typically resolve within approximately 1 week. If the patient continues to exhibit signs and symptoms of illness beyond 10 days or a worsening of symptoms after 7 days, a physician visit is warranted as this may be an indication of a secondary bacterial infection. Ideally, antiviral therapy should not be started until influenza is confirmed via the laboratory. However, therapy should be initiated within 48 hours of illness onset, emphasizing the need for rapid diagnosis. Repeat diagnostic tests to demonstrate clearance of the virus are not necessary.

CONCLUSIONS

Influenza is associated with significant morbidity and mortality and substantial burden to society in terms of both direct and indirect costs. Prevention of influenza by vaccination may yield significant benefit to society in terms of reductions in influenza-related complications, decreased work/school absenteeism, reductions in hospitalizations and deaths, and general cost savings. Two highly effective seasonal influenza vaccines are currently available in the United States, yet influenza remains the leading cause of vaccine-preventable mortality. This underscores the need for tar-

geted efforts toward populations at high risk for serious disease and complications as well as the need for more vaccines, particularly for certain populations (e.g., those younger than 6 months old, those with hypersensitivity to eggs).

Four antiviral drugs are available for treatment and prophylaxis of influenza. Thus, the antiinfluenza antiviral armamentarium is limited and has been further reduced by significant resistance to the adamantanes and oseltamivir in recent years. Importantly, these agents are not a replacement for vaccination but rather an adjunct. Although the neuraminidase inhibitors remain useful as agents for treatment and prophylaxis of influenza, information on the use of these agents in special populations, such as immunocompromised hosts, pregnant women, and very young children, is limited. The best mechanism to decrease the morbidity, mortality, and societal burden associated with influenza remains prevention of the disease through annual vaccination.

ABBREVIATIONS

CDC: U.S. Centers for Disease Control and Prevention

FDA: U.S. Food and Drug Administration

GBS: Guillain-Barré syndrome

HIV: human immunodeficiency virus

LAIV: live-attenuated influenza vaccine

MIV: monovalent inactivated vaccine

mLAIV: monovalent live-attenuated influenza vaccine

TIV: trivalent influenza vaccine

CHAPTER 119

Skin and Soft-Tissue Infections

DOUGLAS N. FISH, SUSAN L. PENDLAND AND LARRY H. DANZIGER

KEY CONCEPTS

1. Folliculitis, furuncles (boils), and carbuncles begin around hair follicles and are caused most often by *Staphylococcus aureus*. Folliculitis and small furuncles are generally treated with warm, moist heat to promote drainage; large furuncles and carbuncles require incision and drainage. A penicillinase-resistant penicillin such as dicloxacillin is commonly used for extensive or serious infections (e.g., fever).
2. Erysipelas, a superficial skin infection with extensive lymphatic involvement, is caused by *Streptococcus pyogenes*. The treatment of choice is penicillin, administered orally or parenterally, depending on the severity of the infection.
3. Impetigo is a superficial skin infection that occurs most commonly in children. It is characterized by fluid-filled vesicles that develop rapidly into pus-filled blisters that rupture to form golden-yellow crusts. Effective therapy includes penicillinase-resistant penicillins (dicloxacillin), first-generation cephalosporins (cephalexin), and topical mupirocin. *S. aureus* is the primary cause of impetigo, with infections caused by community-associated methicillin-resistant *S. aureus* (CA-MRSA) emerging in recent years.
4. Lymphangitis, an infection of the subcutaneous lymphatic channels, is generally caused by *S. pyogenes*. Acute lymphangitis is characterized by the rapid development of fine, red, linear streaks extending from the initial infection site toward the regional lymph nodes, which are usually enlarged and tender. Penicillin is the drug of choice.
5. Cellulitis is an infection of the epidermis, dermis, and superficial fascia most commonly caused by *S. pyogenes* and *S. aureus*. Lesions generally are hot, painful, and erythematous, with nonelevated, poorly defined margins. Treatment generally consists of a penicillinase-resistant penicillin (dicloxacillin) or first-generation cephalosporin (cephalexin) for 5 to 10 days. Trimethoprim-sulfamethoxazole, with or without a β-lactam agent, or doxycycline should be considered for treatment of suspected staphylococcal infections in areas with a high prevalence of CA-MRSA.
6. Necrotizing fasciitis is a rare but life-threatening infection of subcutaneous tissue that results in progressive destruction of superficial fascia and subcutaneous fat. Early and aggressive surgical debridement is an essential part of therapy for treatment of necrotizing fasciitis. Infections caused by *S. pyogenes* or *Clostridium* species should be treated with the combination of penicillin and clindamycin.
7. Diabetic foot infections are managed with a comprehensive treatment approach that includes both proper wound care and antimicrobial therapy. Antimicrobial regimens for diabetic foot infections should include broad-spectrum coverage of staphylococci, streptococci, enteric gram-negative bacilli, and anaerobes. Outpatient therapy with oral antimicrobials should be used whenever possible for less severe infections.
8. Prevention is the single most important aspect in the management of pressure sores. After a sore develops, successful local care includes a comprehensive approach consisting of relief of pressure, proper cleaning (debridement), disinfection, and appropriate antimicrobial therapy if an infection is present. Good wound care is crucial to successful management.
9. All bite wounds (either animal or human) should be irrigated thoroughly with large volumes of sterile normal saline, and the injured area should be immobilized and elevated. Depending on the severity of the bite wound, amoxicillin-clavulanic acid or ampicillin-sulbactam are often used for treatment of animal bites because of their coverage of *Pasteurella multocida*, *S. aureus*, and anaerobes typically present in the oral flora of dogs and cats.
10. Although antimicrobial prophylaxis of dog or cat bites is not recommended routinely, patients with human bite injuries should be given prophylactic antimicrobial therapy for 3 to 5 days. Infected wounds, particularly clenched-fist injuries, should be treated for 7 to 14 days with ampicillin-sulbactam, cefoxitin, or other combination that has activity against *Eikenella corrodens*, *S. aureus*, and β-lactamase–producing anaerobes.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

The skin serves as a barrier between humans and their environment, therefore functioning as a primary defense mechanism against infections. The skin consists of the epidermis, the dermis, and subcutaneous fat. The epidermis is the outermost, nonvascular layer of the skin. It varies in thickness from approximately 0.1 mm on most areas of the body to a maximum of 1.5 mm on the soles of the feet. Although extremely thin, the epidermis is composed of several layers. The innermost layer consists of continuously dividing cells. The outer layers are renewed as cells are

gradually pushed outward. As the cells approach the surface, they become flattened, lose their nuclei, and are filled with keratin. The outermost layer, the stratum corneum, is composed of flattened, cornified, nonnucleated cells. The dermis is the layer of skin directly beneath the epidermis. It consists of connective tissue and contains blood vessels and lymphatics, sensory nerve endings, sweat and sebaceous glands, hair follicles, and smooth muscle fibers. Beneath the dermis is a layer of loose connective tissue containing primarily fat cells. This subcutaneous fat layer is of variable thickness over the body. Beneath the subcutaneous fat lies the fascia, which separates the skin from underlying muscle. It is generally divided into superficial fascia, which is located immediately beneath the skin, and deep fascia, which forms sheaths for muscles.

Skin and soft-tissue infections (SSTIs) may involve any or all layers of the skin, fascia, and muscle. They also may spread far from the initial site of infection and lead to more severe complications, such as endocarditis, gram-negative sepsis, or streptococcal glomerulonephritis. Sometimes the treatment of SSTIs may necessitate both medical and surgical management. This chapter presents details of the pathogenesis and management of some of the most common infections involving the skin and soft tissues. The first part of the chapter discusses a variety of SSTIs that range in severity from superficial to life threatening. The remainder of the chapter discusses diabetic foot infections, pressure sores, and human and animal bites.

EPIDEMIOLOGY

Classification schemes have been developed to describe SSTIs. Bacterial infections of the skin can be classified as primary or secondary (Table 119–1). Primary bacterial infections usually involve areas of previously healthy skin and are caused by a single pathogen. In contrast, secondary infections occur in areas of previously damaged skin and are frequently polymicrobic. SSTIs are also classified as complicated or uncomplicated. Complicated infections are those that involve deeper skin structures (e.g., fascia, muscle layers), require significant surgical intervention, or occur in patients with compromised immune function [e.g., diabetes mellitus, human immunodeficiency virus (HIV) infection].[1]

TABLE 119-1 Bacterial Classification of Important Skin and Soft-Tissue Infections

Primary infections	
Erysipelas	Group A streptococci
Impetigo	*Staphylococcus aureus*, group A streptococci
Lymphangitis	Group A streptococci; occasionally *S. aureus*
Cellulitis	Group A streptococci, *S. aureus* (potentially including methicillin-resistant strains); occasionally other gram-positive cocci, gram-negative bacilli, and/or anaerobes
Necrotizing fasciitis	
Type I	Anaerobes (*Bacteroides* spp., *Peptostreptococcus* spp.) and facultative bacteria (streptococci, Enterobacteriaceae)
Type II	Group A streptococci
Secondary infections	
Diabetic foot infections	*S. aureus*, streptococci, Enterobacteriaceae, *Bacteroides* spp., *Peptostreptococcus* spp., *Pseudomonas aeruginosa*
Pressure sores	*S. aureus*, streptococci, Enterobacteriaceae, *Bacteroides* spp., *Peptostreptococcus* spp., *P. aeruginosa*
Bite wounds	
Animal	*Pasteurella multocida*, *S. aureus*, streptococci, *Bacteroides* spp.
Human	*Eikenella corrodens*, *S. aureus*, streptococci, *Corynebacterium* spp., *Bacteroides* spp., *Peptostreptococcus* spp.
Burn wounds	*P. aeruginosa*, Enterobacteriaceae, *S. aureus*, streptococci

A newer classification system also divides SSTIs into four classes based on severity of signs and symptoms, as well as the presence and stability of any comorbidities.[2] The classification was used to develop an algorithm to help with admission and treatment decisions. Class 1 includes patients who are afebrile and otherwise healthy. These infections are generally managed on an outpatient basis with topical or oral antimicrobials. Class 2 includes patients who are febrile and ill appearing but who have no unstable comorbid conditions. Some class 2 patients may be treated with oral antimicrobials, but most are likely to require some parenteral therapy, either as an outpatient or with short-term hospitalization. Class 3 includes patients having a toxic appearance, unstable comorbidity, or a limb-threatening infection. Class 4 includes patients with sepsis syndrome or another life-threatening infection, such as necrotizing fasciitis. Patients in classes 3 and 4 require hospitalization and parenteral antimicrobial therapy initially but may be candidates for oral or outpatient parenteral therapy once their condition has stabilized. Patients in class 4 also usually require some type of surgical intervention.

SSTIs are among the most common infections seen in both community and hospital settings.[3–5] However, most infections are believed to be mild and are treated in an outpatient setting, making it difficult to accurately quantify community-acquired SSTIs. SSTIs were diagnosed in 0.8% of physician office visits between 1993 and 2005; this corresponded to approximately 82 million diagnoses of SSTI, being more common among elderly patients (70 years of age and older).[3] Another description of office visits among health plan members listed cellulitis and impetigo as the primary diagnoses for 2.2% and 0.3% of patients, respectively.[4] According to an Agency for Healthcare Research and Quality (AHRQ) report, in 2007 SSTIs were responsible for over 600,000 hospitalizations and represented 2.0% of all admissions in males and 1.2% in females.[5]

While the exact incidence of SSTIs is unknown, the frequency of infections caused by invasive group A streptococci and drug-resistant gram-positive cocci has been increasing.[1] Group A streptococci (*Streptococcus pyogenes*) are among the most common etiologic agents of SSTIs. Although they may be found in many mild, superficial skin infections, they are also responsible for life-threatening cases of necrotizing fasciitis.[1] A documented increase in necrotizing fasciitis caused by *S. pyogenes* is a major concern because of the high morbidity and mortality associated with these infections.

Another concerning trend is the increased in vitro resistance reported among other gram-positive bacteria.[1] While the high incidence of nosocomial methicillin-resistant *Staphylococcus aureus* (MRSA) has been a major concern for many years,[6–8] the emergence of community-associated MRSA (CA-MRSA) is even more problematic.[9–15] CA-MRSA strains are characteristically isolated from patients lacking typical risk factors (e.g., prior hospitalization, long-term care facility) and are often susceptible to non-β-lactam antibiotics (trimethoprim-sulfamethoxazole, doxycycline, clindamycin).[9,11,13] They also differ genetically from nosocomial strains of MRSA with methicillin resistance carried on the type IV staphylococcal chromosomal cassette *mec* (SCC*mec*) element of the *mecA* gene. CA-MRSA strains often harbor genes for Panton-Valentine leukocidin, a cytotoxin responsible for leukocyte destruction and tissue necrosis. In contrast, nosocomial strains usually lack genes for Panton-Valentine leukocidin and are associated with SCC*mec* alleles I to III.[10,11,15] Clinicians should suspect CA-MRSA in geographic areas with a high prevalence of these strains or in recurrent or persistent infections that are not responding to appropriate β-lactam therapy. In addition to the emergence of CA-MRSA,

TABLE 119-2 Predominant Microorganisms of Normal Skin

Bacteria
Gram-positive
Coagulase-negative staphylococci
Micrococci (*Micrococcus luteus*)
Corynebacterium species (diphtheroids)
Propionibacterium species
Gram-negative
Acinetobacter species
Fungi
Malassezia species
Candida species

treatment choices for SSTIs have been further complicated by the increased incidence of macrolide-resistant strains of *S. aureus* and *S. pyogenes*.[1,8,11]

ETIOLOGY

The majority of SSTIs are caused by gram-positive organisms present on the skin surface.[1] Gram-positive bacteria (coagulase-negative staphylococci, diphtheroids) are the predominant flora of the skin, with gram-negative organisms (*Escherichia coli* and other Enterobacteriaceae) being relatively uncommon[16] (Table 119–2). *S. aureus*, as well as a variety of gram-negative bacteria, including *Acinetobacter* species, can be found in moist intertriginous areas (e.g., axilla, groin, and toe webs) of the body.[17] *S. aureus* also inhabits the anterior nares of approximately 30% of healthy individuals.[16] Colonization, whether transient or permanent, provides a nidus for infection should the integrity of the epidermis be compromised.

S. aureus and *S. pyogenes* account for the majority of community-acquired SSTIs.[1] Data from large surveillance studies showed *S. aureus* to be the most common cause (45%) of SSTIs in hospitalized patients.[6,7] Also of note in these studies was the 36% incidence of methicillin resistance among strains of *S. aureus*. Other common nosocomial pathogens included *Pseudomonas aeruginosa* (11%), enterococci (9%), and *E. coli* (7%).[6,7]

PATHOPHYSIOLOGY

The skin and subcutaneous tissues normally are extremely resistant to infection but may become susceptible under certain conditions. Even when high concentrations of bacteria are applied topically or injected into the soft tissue, resulting infections are rare.[16] Several host factors act together to confer protection against skin infections. Because the surface of the skin is relatively dry and has a pH of approximately 5.6, it is not conducive to bacterial growth.[16] Continuous renewal of the epidermal layer results in the shedding of keratocytes, as well as skin bacteria. In addition, sebaceous secretions are hydrolyzed to form free fatty acids that strongly inhibit the growth of many bacteria and fungi.[4] Conditions that may predispose a patient to the development of skin infections include (a) high concentrations of bacteria (>10^5 microorganisms), (b) excessive moisture of the skin, (c) inadequate blood supply, (d) availability of bacterial nutrients, and (e) damage to the corneal layer allowing for bacterial penetration.[4,16]

The majority of SSTIs result from the disruption of normal host defenses by processes such as skin puncture, abrasion, or underlying diseases (e.g., diabetes). The nature and severity of the infection depend on both the type of microorganism present and the site of innoculation.

FOLLICULITIS, FURUNCLES, AND CARBUNCLES

1 Folliculitis is inflammation of the hair follicle and is caused by physical injury, chemical irritation, or infection.[4] Infection occurring at the base of the eyelid is referred to as a stye. While folliculitis is a superficial infection with pus present only in the dermis, furuncles and carbuncles occur when a follicular infection extends from around the hair shaft to involve deeper areas of the skin. A furuncle, commonly known as an *abscess* or *boil,* is a walled-off mass of purulent material arising from a hair follicle.[4] The lesions are called *carbuncles* when they coalesce and extend to the subcutaneous tissue. This aggregate of infected hair follicles forms deep masses that generally open and drain through multiple sinus tracts.[4] *S. aureus* is the most common cause of folliculitis, furuncles, and carbuncles. Inadequate chlorine levels in whirlpools, hot tubs, and swimming pools have been responsible for outbreaks of folliculitis caused by *P. aeruginosa*.[17] Outbreaks of furunculosis caused by *S. aureus* and CA-MRSA have been reported in settings involving close contact (such as with families, prisons), especially when skin injury was common (such as with sports). In addition, some individuals experience repeated attacks of furunculosis. The major predisposing factor in this population is the presence of *S. aureus* in the anterior nares.[11]

CLINICAL PRESENTATION

Folliculitis

- Pruritic, erythematous papules typically appear within 48 hours (range: 6 to 72 hours) of exposure to large numbers of organisms.
- Papules evolve into pustules that generally heal in several days.
- Systemic signs such as fever and malaise are uncommon, although they have been reported in cases caused by *P. aeruginosa.*

Furuncles

- Furuncles can occur anywhere on hairy skin but generally develop in areas subject to friction and perspiration.
- Furuncles are discrete lesions, whether occurring as singular or multiple nodules.
- The lesion starts as a firm, tender, red nodule that becomes painful and fluctuant.
- Lesions often drain spontaneously.
- Lesions caused by CA-MRSA often have necrotic centers characteristic of "spider bites."

Carbuncles

- Carbuncles are broad, swollen, erythematous, deep, and painful follicular masses.
- Carbuncles commonly develop on the back of the neck and are more likely to occur in patients with diabetes.
- Unlike folliculitis and furuncles, carbuncles are commonly associated with fever, chills, and malaise.
- Bacteremia with secondary spread to other tissues is common.

TREATMENT

Folliculitis, Furuncles, and Carbuncles

Table 119–3 summarizes evidence-based treatment recommendations from clinical guidelines for SSTIs.[11,18] Treatment of folliculitis generally requires only local measures, such as warm moist compresses or topical therapy (e.g., clindamycin, erythromycin, mupirocin, or benzoyl peroxide).[19] Topical agents generally are applied two to four times daily for 7 days. Small furuncles generally can be treated with moist heat, which promotes localization and drainage of pus.[19] Large and/or multiple furuncles and carbuncles require incision and drainage.[19] Systemic antibiotics are usually not necessary unless accompanied by fever or extensive cellulitis.[11] Treatment of more severe infections generally consists of a penicillinase-resistant penicillin (such as dicloxacillin) or a first-generation cephalosporin (such as cephalexin) for 5 to 10 days (refer to Table 119–4 for adult and pediatric doses). An alternative agent for penicillin-allergic patients is clindamycin. For individuals with nasal colonization, application of mupirocin ointment twice daily in the anterior nares for the first 5 days of each month decreases recurrent furunculosis by almost half.[11] In addition, a single oral daily dose of clindamycin 150 mg for 3 months reduced recurrent infections caused by susceptible strains of *S. aureus* by approximately 80%.[11]

EVALUATION OF THERAPEUTIC OUTCOMES

Many follicular infections resolve spontaneously without medical or surgical intervention. Lesions should be incised if they do not respond to a few days of moist heat and nonprescription topical agents. Following drainage, most lesions begin to heal within several days without antimicrobial therapy. Any patient who is unresponsive to several days of therapy with a penicillinase-resistant penicillin or first-generation cephalosporin should have a culture and sensitivity performed because of the increasing frequency of CA-MRSA.

ERYSIPELAS

2 Erysipelas is an infection of the more superficial layers of the skin and cutaneous lymphatics.[20] The intense red color and burning pain associated with this skin infection led to the common name of "St. Anthony's fire." The infection is almost always caused by β-hemolytic streptococci, with the organisms gaining access via small breaks in the skin. Group A streptococci (*S. pyogenes*) are responsible for most infections.[11,19,20] Infections are more common

TABLE 119-3 Evidence-Based Recommendations for Treatment of Skin and Soft-Tissue Infections[11,19]

Recommendations	Recommendation Grade
Folliculitis, furuncles, carbuncles	
Folliculitis and small furuncles can be treated with moist heat; large furuncles and carbuncles require incision and drainage. Antimicrobial therapy is unnecessary unless extensive lesions or fever are present.	EIII
Erysipelas	
Most infections are caused by *Streptococcus pyogenes*. Penicillin (oral or intravenous depending on clinical severity) is the drug of choice.	AI
If *Staphylococcus aureus* is suspected, a penicillinase-resistant penicillin or first-generation cephalosporin should be used.	AI
Impetigo	
S. aureus accounts for the majority of infections; consequently, a penicillin-resistant penicillin or first-generation cephalosporin is recommended.	AI
Topical therapy with mupirocin is equivalent to oral therapy.	AI
Cellulitis	
Mild-moderate infections can generally be treated with oral agents (dicloxacillin, cephalexin, clindamycin) unless resistance is high in the community.	AI
Serious infections should be treated intravenously with a penicillinase-resistant penicillin (nafcillin) or first-generation cephalosporin (cefazolin). Patients with penicillin allergies should be treated with vancomycin or clindamycin.	AI
Vancomycin, linezolid, and daptomycin should be used to treat serious infections caused by methicillin-resistant *S. aureus*.	AI
Necrotizing fasciitis	
Early and aggressive surgical debridement of all necrotic tissue is essential.	AIII
Necrotizing fasciitis caused by *S. pyogenes* should be treated with the combination of clindamycin and penicillin.	AII
Clostridial gas gangrene (myonecrosis) should be treated with clindamycin and penicillin.	BIII
Diabetic foot infections	
Many mild to moderate infections can be treated with oral agents that possess high bioavailability.	AII
All severe infections should be treated with intravenous therapy. After initial response, step-down therapy to oral agents can be used.	CIII
Broad-spectrum antimicrobial therapy is not generally required, except for some severe cases.	BIII
Definitive therapy should be based on results of appropriately collected cultures and sensitivities, as well as clinical response to empiric antimicrobial agents.	CIII
Optimal wound care, in additional to appropriate antimicrobial therapy, is essential for wound healing.	AI
Animal bites	
Many bite wounds can be treated on an outpatient basis with amoxicillin-clavulanic acid.	BII
Serious infections requiring intravenous antimicrobial therapy can be treated with a β-lactam/β-lactamase inhibitor combination or second-generation cephalosporin with activity against anaerobes (cefoxitin).	BII
Penicillinase-resistant penicillins, first-generation cephalosporins, macrolides, and clindamycin should not be used for treatment because of their poor activity against *Pasteurella multocida*.	DIII
Human bites	
Antimicrobial therapy should provide coverage against *Eikenella corrodens*, *S. aureus*, and β-lactamase–producing anaerobes.	BIII

Strength of recommendation: A, good evidence for use; B, moderate evidence for use; C, poor evidence for use, optional; D, moderate evidence to support not using; E, good evidence to support not using. Quality of evidence: I, evidence from ≥1 properly randomized, controlled trials; II, evidence from ≥1 well-designed clinical trials without randomization, case-controlled analytic studies, multiple time series, or dramatic results from uncontrolled experiments; III, evidence from expert opinion, clinical experience, descriptive studies, or reports of expert committees.

TABLE 119-4 Recommended Drugs and Dosing Regimens for Outpatient Treatment of Mild–Moderate Skin and Soft-Tissue Infections

Infection	Oral Adult Dose	Oral Pediatric Dose
Folliculitis	None; warm saline compresses usually sufficient	
Furuncles and carbuncles	Dicloxacillin 250–500 mg every 6 h Cephalexin 250–500 mg every 6 h Clindamycin 300–600 mg every 6–8 h[a]	Dicloxacillin 25–50 mg/kg in four divided doses Cephalexin 25–50 mg/kg in four divided doses Clindamycin 10–30 mg/kg/day in three to four divided doses[4]
Erysipelas	Procaine penicillin G 600,000 units intramuscularly every 12 h Penicillin VK 250–500 mg every 6 h Clindamycin 150–300 mg every 6–8 h[a] Erythromycin 250–500 mg every 6 h[a]	Penicillin VK 25,000–90,000 units/kg in four divided doses Clindamycin 10–30 mg/kg in three to four doses[a] Erythromycin 30–50 mg/kg in four divided doses[a]
Impetigo	Dicloxacillin 250–500 mg every 6 h Cephalexin 250–500 mg every 6 h Cefadroxil 500 mg every 12 h Clindamycin 150–300 mg every 6–8 h[a] Mupirocin ointment every 8 h[a] Retapamulin ointment every 12 h[a]	Dicloxacillin 25–50 mg/kg in four divided doses Cephalexin 25–50 mg/kg in two to four divided doses Cefadroxil 30 mg/kg in two divided doses Clindamycin 10–30 mg/kg/day in three to four divided doses[a] Mupirocin ointment every 8 h[a] Retapamulin ointment every 12 h[a]
Lymphangitis	Initial intravenous therapy, followed by penicillin VK 250–500 mg every 6 h Clindamycin 150–300 mg every 6–8 h[a]	Initial intravenous therapy, followed by penicillin VK 25,000–90,000 units/kg in four divided doses Clindamycin 10–30 mg/kg/day in three to four divided doses[a]
Diabetic foot infections	Amoxicillin-clavulanic acid 875 mg/125 mg every 12 h Fluoroquinolone (levofloxacin 750 mg every 24 h or moxifloxacin 400 mg every 24 h) + metronidazole 250–500 mg every 8 h or clindamycin 300–600 mg every 6–8 h[a]	
Animal bite	Amoxicillin-clavulanic acid 875 mg/125 mg every 12 h Doxycycline 100–200 mg every 12 h[a] Dicloxacillin 250–500 mg every 6 h + penicillin VK 250–500 mg every 6 h Cefuroxime axetil 500 mg every 12 h + metronidazole 250–500 mg every 8 h or clindamycin 300–600 mg every 6–8 h Fluoroquinolone (levofloxacin 500–750 mg every 24 h or moxifloxacin 400 mg every 24 h) or clindamycin 300-600 mg every 6–8 h[a] Erythromycin 500 mg every 6 h + metronidazole 250–500 mg every 8 h or clindamycin 300–600 mg every 6–8 h[a]	Amoxicillin-clavulanic acid 40 mg/kg (of the amoxicillin component) in two divided doses Dicloxacillin 25–50 mg/kg in four divided doses + penicillin VK 40,000–90,000 units/kg in four divided doses Cefuroxime axetil 20–30 mg/kg in two divided doses + metronidazole 30 mg/kg in three to four divided doses or clindamycin 10–30 mg/kg/day in three to four divided doses Trimethoprim-sulfamethoxazole 4–6 mg/kg (of the trimethoprim component) every 12 h + metronidazole 30 mg/kg in three to four divided doses or clindamycin 10–30 mg/kg/day in three to four divided doses[a] Erythromycin 30–50 mg/kg in four divided doses + every 12 h + metronidazole 30 mg/kg in three to four divided doses or clindamycin 10–30 mg/kg/day in three to four divided doses[a]
Human bite	Amoxicillin-clavulanic acid 875 mg/125 mg every 12 h Doxycycline 100–200 mg every 12 h[a] Dicloxacillin 250–500 mg every 6 h + penicillin VK 250–500 mg every 6 h Cefuroxime axetil 500 mg every 12 h metronidazole 250–500 mg every 8 h or clindamycin 300–600 mg every 6–8 h Fluoroquinolone (levofloxacin 500–750 mg every 24 h or moxifloxacin 400 mg every 24 h) + metronidazole 250–500 mg every 8 h or clindamycin 300–600 mg every 6–8 h[a]	Amoxicillin-clavulanic acid 40 mg/kg (of the amoxicillin component) in two divided doses Dicloxacillin 25–50 mg/kg in four divided doses + penicillin VK 40,000–90,000 units/kg in four divided doses Cefuroxime axetil 20–30 mg/kg in two divided doses + metronidazole 30 mg/kg in three to four divided doses or clindamycin 10–30 mg/kg/day in three to four divided doses Trimethoprim-sulfamethoxazole 4–6 mg/kg (of the trimethoprim component) every 12 h + metronidazole 30 mg/kg in three to four divided doses or clindamycin 10–30 mg/kg/day in 3–4 divided doses[a]

[a]Recommended for patients with penicillin allergy.

in infants, young children, the elderly, and patients with nephrotic syndrome.[19] Erysipelas also commonly occurs in areas of preexisting lymphatic obstruction or edema.[19] Diagnosis is made on the basis of the characteristic lesion.

CLINICAL PRESENTATION

General

- The lower extremities are the most common sites for erysipelas.

Symptoms

- Patients often experience flu-like symptoms (fever, malaise) prior to the appearance of the lesion.
- The infected area is described as painful or as a burning pain.

Signs

- The lesion is bright red and edematous, often with lymphatic streaking.
- Temperature is often mildly elevated.

Laboratory Tests

- The causative organism usually cannot be cultured from the surface skin but sometimes may be aspirated from the edge of the advancing lesion.
- Cultures may be considered in more severe cases or those with atypical clinical findings such as fluid-filled blisters.

Other Diagnostic Tests

- A complete blood count is often performed because leukocytosis is common.
- C-reactive protein is also generally elevated.

TREATMENT

Erysipelas

The goal of treatment of erysipelas is rapid eradication of the infection. Mild to moderate cases of erysipelas are treated with intramuscular procaine penicillin G or penicillin VK for 7 to 10 days (see Table 119–4)[19,20] Penicillin-allergic patients can be treated with clindamycin or erythromycin. For more serious infections, the patient should be hospitalized and aqueous penicillin G 2 to 8 million units daily administered intravenously.[19,20] Marked improvement usually is seen within 48 hours, and the patient often may be switched to oral penicillin to complete the course of therapy. Although one study has shown that the median time for cure, intravenous antibiotics, and hospital stay was reduced in patients receiving prednisolone in addition to antibiotics, further studies are needed before corticosteroids can be recommended for routine use.[11,19]

EVALUATION OF THERAPEUTIC OUTCOMES

Erysipelas generally responds quickly to appropriate antimicrobial therapy. Temperature and white blood cell count should return to normal within 48 to 72 hours. Erythema, edema, and pain also should resolve gradually.

IMPETIGO

3 Impetigo is a superficial skin infection that is seen most commonly in children.[21] The infection is generally classified as bullous or nonbullous based on clinical presentation.[4] Impetigo is most common during hot, humid weather, which facilitates microbial colonization of the skin.[19] Minor trauma, such as scratches or insect bites, allows entry of organisms into the superficial layers of skin, and infection ensues.[19] Impetigo is highly communicable and readily spreads through close contact, especially among siblings and children in daycare centers and schools.[19,20]

Although historically caused by *S. pyogenes, S. aureus* has also emerged as a principle cause of impetigo (either alone or in combination with *S. pyogenes*).[21] The bullous form is caused by strains of *S. aureus* capable of producing exfoliative toxins.[21] The bullous form most frequently affects neonates and accounts for approximately 10% of all cases of impetigo.[19,21]

CLINICAL PRESENTATION

General

- Exposed skin, especially the face, is the most common site for impetigo.

Symptoms

- Pruritus is common, and scratching of the lesions may further spread infection through excoriation of the skin.
- Other systemic signs of infection are minimal.
- Weakness, fever, and diarrhea sometimes are seen with bullous impetigo.

Signs

- Nonbullous impetigo manifests initially as small, fluid-filled vesicles.
- These lesions rapidly develop into pus-filled blisters that rupture readily.
- Purulent discharge from the lesions dries to form golden-yellow crusts that are characteristic of impetigo.
- In the bullous form of impetigo, the lesions begin as vesicles and turn into bullae containing clear yellow fluid.
- Bullae soon rupture, forming thin, light brown crusts.
- Regional lymph nodes may be enlarged.

Laboratory Tests

- Cultures should be collected.
- Crusted tops of lesions should be raised so that purulent material at the base of the lesion can be cultured.
- Cultures should not be collected from open, draining skin pustules because they may be colonized with staphylococci and other normal skin flora.

Other Diagnostic Tests

- A complete blood count is often performed because leukocytosis is common.

TREATMENT

Impetigo

Although impetigo may resolve spontaneously, antimicrobial treatment is indicated to relieve symptoms, prevent formation of new lesions, and prevent complications such as cellulitis. Penicillinase-resistant penicillins (such as dicloxacillin) are preferred for treatment because of the increased incidence of infections caused by *S. aureus*.[11] First-generation cephalosporins (such as cephalexin) are also commonly used. Penicillin, administered as a single intramuscular dose of benzathine penicillin G (300,000 to 600,000 units in children, 1.2 million units in adults) or as oral penicillin VK, is effective for infections known to be caused by *S. pyogenes*. Penicillin-allergic patients can be treated with clindamycin. The duration of therapy is 7 to 10 days. Topical therapy with mupirocin ointment or retapamulin ointment (applied three times daily or twice daily, respectively, for 7 days) is also effective for mild cases.[11] With proper treatment, healing of skin lesions generally is rapid and occurs without residual scarring. Removal of crusts by soaking in soap and warm water also may be helpful in providing symptomatic relief.[19,20]

EVALUATION OF THERAPEUTIC OUTCOMES

Clinical response should be seen within 7 days of initiating antimicrobial therapy for impetigo. Treatment failures could be a result of noncompliance or antimicrobial resistance. A followup culture of exudates should be collected for culture and sensitivity, with treatment modified accordingly.[21]

LYMPHANGITIS

4 Acute lymphangitis is an inflammation involving the subcutaneous lymphatic channels. Lymphangitis usually occurs secondary to puncture wounds, infected blisters, or other skin lesions. Most infections are caused by *S. pyogenes*.[22]

CLINICAL PRESENTATION

General

- Lymphadenitis (acute or chronic inflammation of the lymph nodes) also may occur when microorganisms reach the lymph nodes and elicit an inflammatory response.

Symptoms

- Systemic manifestations of infection (i.e., fever, chills, malaise, and headache) often develop rapidly before any sign of infection is evident at the initial site of inoculation or even after the initial lesion has subsided.
- Systemic symptoms often are more profound than would be expected based on examination of the cutaneous lesion.

Signs

- Identification of a peripheral lesion associated with proximal red linear streaks directed toward the regional lymph nodes is diagnostic of acute lymphangitis.
- Lymph nodes usually are enlarged and tender.
- Peripheral edema of the involved extremity often is present.
- Thrombophlebitis and acute lymphangitis in the lower extremities may be confused because both are associated with red linear streaking and tender areas; however, in thrombophlebitis, no portal of entry is identifiable.

Laboratory Tests

- Cultures of the affected lesions often yield negative results because the infection resides within the lymphatic channels.
- Offending pathogens often can be identified by Gram stain of the initial lesion if done early in the course of the disease.

Other Diagnostic Tests

- A complete blood count frequently is performed because leukocytosis is common.

TREATMENT

Lymphangitis

The goal of therapy for lymphangitis is rapid eradication of infection and prevention of further systemic complications. Penicillin is the antibiotic of choice. Because these infections are potentially serious and rapidly progressive, initial treatment should be with intravenous penicillin G 1 to 2 million units every 4 to 6 hours. Parenteral treatment should be continued for 48 to 72 hours, followed by oral penicillin VK for a total of 10 days.[22] Nondrug therapy includes immobilization and elevation of the affected extremity and warm-water soaks every 2 to 4 hours.[22] For penicillin-allergic patients, clindamycin may be used.

EVALUATION OF THERAPEUTIC OUTCOMES

Lymphangitis usually responds rapidly to appropriate therapy; signs and symptoms often are decreased markedly or absent within 24 hours of starting antibiotics.

CELLULITIS

5 Cellulitis is an acute infectious process that represents a serious type of SSTI. Cellulitis initially affects the epidermis and dermis and may spread subsequently within the superficial fascia. Cellulitis is considered a serious disease because of the propensity of the infection to spread through lymphatic tissue and to the bloodstream. *S. pyogenes* and *S. aureus* are the most frequent bacterial causes. However, many bacteria have been implicated in various types of cellulitis (see Table 119–1). Approximately 4 million patients were hospitalized for cellulitis between 1998 and 2006, representing 10% of all infection-related admissions.[23] The rising incidence of infections caused by MRSA is a major concern in both the community and hospital settings.[6,7,9–15]

Injection-drug users are predisposed to a number of infectious complications, including abscess formation and cellulitis at the site of injection.[24] These SSTIs are located most frequently on the upper extremities and often are polymicrobic in nature.[25] Infecting organisms are believed to originate from the skin and/or oropharynx, as well as from contaminated needles, syringes, and diluents.[25] *S. aureus* is the most common pathogen isolated from these infections. The incidence of MRSA is also rising in SSTIs for injection-drug users.[26,27] Anaerobic bacteria, especially oropharyngeal anaerobes, are also found commonly, particularly in polymicrobic infections.[25] Outbreaks caused by *Clostridium* species have also been reported in injection-drug users, particularly as a consequence of injection of contaminated black-tar heroin.[28,29]

Acute cellulitis with mixed aerobic and anaerobic pathogens may occur in diabetics, following traumatic injuries, at sites of surgical incisions to the abdomen or perineum, or where host defenses have been otherwise compromised (vascular insufficiency). In older patients, cellulitis of the lower extremities also may be complicated by thrombophlebitis. Other complications of cellulitis include local abscess, osteomyelitis, and septic arthritis.[11,30]

CLINICAL PRESENTATION

General

- There is usually a history of an antecedent wound from a minor trauma, abrasion, ulcer, or surgery.
- Because these infections occur often for patients with alterations in host defense mechanisms, poor nutrition, or both, systemic findings such as hypotension, dehydration, and altered mental status are common.

Symptoms

- Patients often experience fever, chills, or malaise and complain that the affected area feels hot and painful.

Signs

- Cellulitis is characterized by erythema and edema of the skin.
- Lesions, which may be extensive, are nonelevated and have poorly defined margins.
- Affected areas generally are warm to touch.
- Inflammation generally is present with little or no necrosis or suppuration of soft tissue.
- Tender lymphadenopathy associated with lymphatic involvement is common.

Laboratory Tests

- Cultures should be collected when possible.
- A Gram stain of fluid obtained by injection and aspiration of 0.5 mL of saline (using a small 22-gauge needle) into the advancing edge of the lesion may aid the microbiologic diagnosis but often yields negative results.
- Diagnosis usually is made on clinical grounds, that is, the appearance of the lesion.

Other Diagnostic Tests

- A complete blood count frequently is performed because leukocytosis is common.
- Because bacteremia may be present in as many as 30% of cases of cellulitis, blood cultures may be useful for diagnosis of some patients.

TREATMENT

Cellulitis

The goal of therapy of acute bacterial cellulitis is rapid eradication of the infection and prevention of further complications. Antimicrobial therapy is directed against the type of bacteria either documented or suspected to be present based on the clinical presentation. Local care of cellulitis includes elevation and immobilization of the involved area to decrease swelling. Cool sterile saline dressings may decrease pain and can be followed later with moist heat to aid in localization of the cellulitis. Surgical intervention (incision and drainage) as a mode of therapy is rarely indicated in the treatment of uncomplicated cellulitis. The use of inappropriate antibiotic therapy for cellulitis is associated with significantly higher risk of clinical treatment failures.[30] Therefore, in the selection of antibiotics for treatment of cellulitis, particular attention must be paid to patients with risk factors for more atypical or resistant bacterial pathogens (e.g., gram-negative bacteria, anaerobes, MRSA).

Because staphylococcal and streptococcal cellulitis are indistinguishable clinically,[1,20] administration of a penicillinase-resistant penicillin (nafcillin or oxacillin) or first-generation cephalosporin (cefazolin) is recommended until a definitive diagnosis, by skin or blood cultures, can be made (Table 119–5).[2,11,19,20,30] Mild to moderate infections not associated with systemic symptoms may

TABLE 119-5 Initial Treatment Regimens for Cellulitis Caused by Various Pathogens

Antibiotic	Adult Dose and Route	Pediatric Dose and Route
Staphylococcal or unknown gram-positive infection		
Mild infection	Dicloxacillin 0.25–0.5 g orally every 6 h[a,b]	Dicloxacillin 25–50 mg/kg/day orally in four divided doses[a,b]
Mild infection, suspected CA-MRSA	Trimethoprim-sulfamethoxazole 80 mg/160 mg orally every 8–12 h Doxycycline 100 mg orally every 12 h	Trimethoprim-sulfamethoxazole 4 mg/kg (trimethoprim component) orally every 8–12 h
Moderate to severe infection	Nafcillin or oxacillin 1–2 g IV every 4–6 h[a,b]	Nafcillin or oxacillin 150–200 mg/kg/day (not to exceed 12 g/24 h) IV in four to six equally divided doses[a,b]
Streptococcal (documented)		
Mild infection	Penicillin VK 0.5 g orally every 6 h[a] or procaine penicillin G 600,000 units IM every 8–12 h[a]	Penicillin VK 125–250 mg orally every 6–8 h, or procaine penicillin G 25,000–50,000 units/kg (not to exceed 600,000 units) IM every 8–12 h[a]
Moderate to severe infection	Aqueous penicillin G 1–2 million units IV every 4–6 h[a,c]	Aqueous penicillin G 100,000–200,000 units/kg/day IV in four divided doses[a]
Gram-negative bacilli		
Mild infection	Cefaclor 0.5 g orally every 8 h[d] or cefuroxime axetil 0.5 g orally every 12 h[d]	Cefaclor 20–40 mg/kg/day (not to exceed 1 g) orally in three divided doses or cefuroxime axetil 0.125–0.25 g (tablets) orally every 12 h
Moderate to severe infection	Aminoglycoside[e] or IV cephalosporin (first-or second-generation depending on severity of infection or susceptibility pattern)[d]	Aminoglycoside[e] or intravenous cephalosporin (first- or second-generation depending on severity of infection or susceptibility pattern)
Polymicrobic infection without anaerobes		
	Aminoglycoside[e] + penicillin G 1–2 million units every 4–6 h or a semisynthetic penicillin (nafcillin 1–2 g every 4–6 h) depending on isolation of staphylococci or streptococci[b]	Aminoglycoside[e] + penicillin G 100,000–200,000 units/kg/day IV in four divided doses or a semisynthetic penicillin [nafcillin 150–200 mg/kg/day (not to exceed 12 g/24 h)] IV in four to six equally divided doses] depending on isolation of staphylococci or streptococci[b]
Polymicrobic infection with anaerobes		
Mild infection	Amoxicillin/clavulanate 0.875 g orally every 12 h or a fluoroquinolone (ciprofloxacin 0.4 g orally every 12 h or levofloxacin 0.5–0.75 g orally every 24 h) plus clindamycin 0.3–0.6 g orally every 8 h or metronidazole 0.5 g orally every 8 h	Amoxicillin/clavulanic acid 20 mg/kg/day orally in three divided doses
Moderate to severe infection	Aminoglycoside[e,f] + clindamycin 0.6–0.9 g IV every 8 h or metronidazole 0.5 g IV every 8 h Or Monotherapy with second- or third-generation cephalosporin (cefoxitin 1–2 g IV every 6 h or ceftizoxime 1–2 g IV every 8 h) Or Monotherapy with imipenem 0.5 g IV every 6–8 h, meropenem 1 g IV every 8 h, ertapenem 1 g IV every 24 h, doripenem 0.5 g every 8 h, extended-spectrum penicillins with a β-lactamase inhibitor (piperacillin/tazobactam 4.5 g IV every 6 h), or tigecycline 100 mg IV as loading dose, then 50 mg IV every 12 h	Aminoglycoside[e] plus clindamycin 15 mg/kg/day IV in three divided doses or metronidazole 30–50 mg/kg/day IV in three divided doses

IM, intramuscularly; IV, intravenous; CA-MRSA, community-associated methicillin-resistant *Staphylococcus aureus*.

[a]For penicillin-allergic patients, use clindamycin 150–300 mg orally every 6–8 h (pediatric dosing: 10–30 mg/kg/day in three to four divided doses).

[b]For methicillin-resistant staphylococci, use vancomycin 0.5–1 g every 6–12 h (pediatric dosing 40 mg/kg/day in divided doses) with dosage adjustments made for renal dysfunction.

[c]For type II necrotizing fasciitis, use clindamycin 0.6–0.9 g IV every 8 h (in children, clindamycin 15 mg/kg/day IV in 3 divided doses).

[d]For penicillin-allergic adults, use a fluoroquinolone (ciprofloxacin 0.5–0.75 g orally every 12 h or 0.4 g IV every 12 h; levofloxacin 0.5–0.75 g orally or IV every 24 h; or moxifloxacin 0.4 g orally or IV every 24 h).

[e]Gentamicin or tobramycin, 2 mg/kg loading dose, then maintenance dose as determined by serum concentrations.

[f]A fluoroquinolone or aztreonam 1 g IV every 6 h may be used in place of the aminoglycoside in patients with severe renal dysfunction or other relative contraindications to aminoglycoside use.

be treated orally with dicloxacillin or cephalexin. Other oral cephalosporins, such as cefadroxil, cefaclor, cefprozil, cefpodoxime proxetil, and cefdinir, are also effective in the treatment of cellulitis but are more expensive.[11,20,30] If documented to be a mild cellulitis secondary to streptococci, oral penicillin VK or intramuscular procaine penicillin may be administered. More severe infections, either staphylococcal or streptococcal, should be treated initially with intravenous antibiotic regimens. Ceftriaxone 50 to 100 mg/kg as a single daily dose is efficacious in the treatment of cellulitis in pediatric patients.[31] The usual duration of therapy for cellulitis is 5 to 10 days.[11,19,30]

In penicillin-allergic patients, oral or parenteral clindamycin may be used.[1,2] Alternatively, a first-generation cephalosporin may be used cautiously for patients without a history of immediate or anaphylactic reactions to penicillin. In severe cases in which cephalosporins can not be used because of suspected and/or documented MRSA or severe β-lactam allergies, vancomycin should be administered.[2,11]

Infection with CA-MRSA should be considered for patients with skin abscesses, subjective history of insect bites, or more severe infections.[30,32] Appropriate clinical specimens for culture and susceptibility testing should be collected whenever possible for such patients.[30,32] Incision and drainage is the primary therapy for CA-MRSA infections such as furuncles and small abscesses in otherwise uncomplicated patients with mild infections, and systemic antibiotic therapy is often unnecessary in such cases. Antibiotic therapy should be added to incision and drainage for patients with more complicated cases such as rapidly progressive infection; abscesses in association with more severe cellulitis; signs and symptoms of systemic illness; complicating factors such as extreme age, comorbidities, or immunosuppression; or lack of response to previous drainage alone.[30,32–35]

Although the most optimal treatment for CA-MRSA infections is not known, initial therapy with trimethoprim-sulfamethoxazole, doxycycline, or clindamycin appears to be effective in most cases and should be considered in geographic areas in which CA-MRSA infections are commonly encountered.[9,13,14,32–35] Hospital-acquired strains of MRSA tend to be more antibiotic resistant and vancomycin is a more appropriate choice for initial treatment of patients in whom hospital-acquired MRSA is a suspected or documented pathogen. Alternative agents for infections with resistant gram-positive bacteria such as MRSA and vancomycin-resistant enterococci include linezolid, quinupristin-dalfopristin, daptomycin, tigecycline, and telavancin.[1,2,32–39] The excellent activity of these drugs against resistant gram-positive pathogens but significantly higher cost make them most appropriate for treatment of complicated or refractory infections, or those documented as caused by multidrug-resistant pathogens, rather than as initial therapy. The availability of orally administered linezolid may provide a cost-effective "step-down" option for many patients with more complicated infections and/or those patients who require initial hospitalization as an alternative to prolonged treatment with parenteral agents.[40] Tigecycline may be considered in complicated infections, particularly those in which the presence of mixed gram-negative and/or anaerobic pathogens is suspected or documented alongside resistant gram-positive bacteria.[38,39]

CLINICAL CONTROVERSY

Because numerous studies have documented the increasing prevalence of CA-MRSA, there is considerable debate regarding the optimal treatment recommendations for empiric antimicrobial therapy of SSTIs.[9,13,14,32–35]

Trimethoprim-sulfamethoxazole has excellent in vitro activity against CA-MRSA, but few clinical trials have been published that correlate susceptibility data with clinical outcomes. Another concern is the lack of activity of trimethoprim-sulfamethoxazole against *S. pyogenes*, another organism commonly found in SSTIs. The combination of trimethoprim-sulfamethoxazole plus a β-lactam antibiotic has been suggested when empiric therapy is needed for coverage of both organisms, but there are no data confirming that combination therapy improves outcomes.[9,13,14,32–35] Doxycycline has activity against both *S. aureus* and *S. pyogenes,* but only limited data suggests efficacy for SSTIs caused by CA-MRSA.[41,42] The optimal role of doxycycline relative to trimethoprim-sulfamethoxazole remains unclear. Clindamycin is often active against CA-MRSA, but there is concern of inducible clindamycin resistance during therapy, and the role of this agent is still not well-defined.[9,13,14,32–35]

The carbapenems (i.e., imipenem, meropenem, ertapenem, and doripenem) and the β-lactam–β-lactamase inhibitor combination antibiotics (ampicillin-sulbactam, ticarcillin-clavulanic acid, and piperacillin-tazobactam) appear to be equivalent to standard therapies for adults.[1,2,11,43] However, the greater cost of these newer agents without increased efficacy compared with other reliable regimens, particularly given the increasing problem of MRSA, makes them less desirable for empiric therapy.[1,2,11]

For cellulitis caused by gram-negative bacilli or a mixture of microorganisms, immediate antimicrobial chemotherapy, as determined by Gram stain, is essential (see Table 119–5). Surgical debridement of necrotic tissue and drainage also may be appropriate. Gram-negative cellulitis may be treated appropriately with an aminoglycoside (such as gentamicin or tobramycin), or first- or second-generation cephalosporin (such as cephalexin or cefaclor/cefuroxime, respectively). If gram-positive aerobic bacteria are also present, penicillin G or a penicillinase-resistant penicillin should be added to the regimen. Ceftazidime and the fluoroquinolones are effective in the treatment of cellulitis caused by both gram-negative and gram-positive bacteria.[1,2,11,43]

CLINICAL CONTROVERSY

Fluoroquinolones are attractive options for SSTIs due to a broad spectrum of activity and availability of highly bioavailable oral agents. They also have demonstrated efficacy similar to parenteral β-lactam antibiotics in the treatment of SSTIs, including diabetic foot infections.[1,11,18,43] Lower eradication rates for streptococci have been reported with fluoroquinolones when compared with cephalexin and other agents in the treatment of uncomplicated SSTIs.[1,11,44] Levofloxacin and moxifloxacin are approved by the Food and Drug Administration for both uncomplicated and complicated SSTIs. However, the use of fluoroquinolones is of concern because of increasing resistance among both gram-positive and gram-negative bacteria.[1,11,45,46] Despite potential in vitro susceptibility, the optimal role of the fluoroquinolones for treatment of MRSA infections is not well-defined and they are not routinely recommended due to inconsistent efficacy and concerns regarding resistance.[9,11,13,14,32–35] Also, fluoroquinolones are not approved for use in children because of toxicity concerns.

Because some infections may be polymicrobic, antibiotic therapy may need to be broadened to include agents with good activity against anaerobic bacteria. Many different treatment regimens are possible depending on the bacteriology of the lesion (see Table 119–5). Usually an aminoglycoside combined with an antianaerobic cephalosporin (such as cefoxitin or ceftizoxime), extended-spectrum penicillin (such as piperacillin), or clindamycin is used. Second- or third-generation cephalosporins (such as cefaclor/cefuroxime or ceftizoxime, respectively) have been suggested as single-agent therapy in certain instances.[1,2,11] Monotherapy with a β-lactam plus β-lactamase inhibitor combination antibiotic (such as piperacillin-tazobactam) or a carbapenem (such as imipenem or ertapenem) also may be appropriate for seriously ill patients.[1,2,11] Therapy should be 10 to 14 days in duration.

Because gram-negative and mixed aerobic–anaerobic cellulitis can progress quickly to serious tissue invasion, therapeutic intervention should be immediate. If treated early, a rapid response can be seen. Unfortunately, because these infections often occur for patients with compromised immune defenses, they may still progress, even with therapeutic intervention. If the infectious process is secondary to a systemic cause (e.g., diabetes), the treatment course often is prolonged and may be associated with high morbidity and mortality.

Infections in injection-drug users generally are treated similarly to those in other types of patients.[11,12,25] It is important that blood cultures be obtained in these cases because 25% to 35% of patients may be bacteremic.[1,11,25] Also, patients should be assessed for the presence of abscesses; incision, drainage, and culture of these lesions are of extreme importance.[11] Initial antimicrobial therapy while awaiting culture results of abscesses should include broad coverage for gram-negative and anaerobic organisms, in addition to *S. aureus* (including MRSA in areas with high prevalence) and streptococci.[1,2,11,25]

EVALUATION OF THERAPEUTIC OUTCOMES

If treated promptly with appropriate antibiotics, the majority of patients with cellulitis are cured rapidly. Culture and sensitivity results should be evaluated carefully both for the adequacy of culture material and the presence of resistant organisms. Additional high-quality samples for culture may be needed for microbiologic analysis. Failure to respond to therapy also may be indicative of an underlying local or systemic problem or a misdiagnosis.

NECROTIZING SOFT-TISSUE INFECTIONS

Necrotizing soft-tissue infections consist of a group of highly lethal infections that require early and aggressive surgical debridement in addition to appropriate antibiotics and intensive supportive care.[47–49] A number of different terms have been used to classify necrotizing infections based on factors such as predisposing conditions, onset of symptoms, pain, skin appearance, etiologic agent, gas production, muscle involvement, and systemic toxicity. While many types of necrotizing soft-tissue infections have been designated as unique infectious processes, they all share similar pathophysiologies, clinical features, and treatment approaches.[47–49] The major clinical entities of necrotizing infections are *necrotizing fasciitis* and *clostridial myonecrosis* (gas gangrene).[47,48]

6 Necrotizing fasciitis is a rare but very severe infection of the subcutaneous tissue that may be caused by aerobic and/or anaerobic bacteria and results in progressive destruction of the superficial fascia and subcutaneous fat. It is generally characterized as one of two different types based on bacterial etiology. Type I necrotizing fasciitis generally occurs after trauma and surgery and involves a mixture of anaerobes (*Bacteroides, Peptostreptococcus*) and facultative bacteria (streptococci and members of Enterobacteriaceae) that act synergistically to cause destruction of fat and fascia. Type I necrotizing fasciitis is also being reported more commonly among injection-drug users.[47–49] In type I infections, the skin may be spared, and the speed at which the infection spreads is somewhat slower than type II. Necrotizing fasciitis affecting the male genitalia is termed *Fournier gangrene.* Type II necrotizing fasciitis is caused by virulent strains of *S. pyogenes* and is more commonly referred to as *streptococcal gangrene.* This type of infection has often been called *flesh-eating bacteria* by the lay press. Unlike previous reports of streptococcal gangrene that affected older individuals with underlying diseases, recent reports have occurred primarily in young, previously healthy adults following some type of minor trauma. It differs from the polymicrobial type I infections in its clinical presentation. Type II infections have rapidly extending necrosis of subcutaneous tissues and skin, gangrene, severe local pain, and systemic toxicity.[20,47,48] Type II infections are also highly associated with an early onset of shock and organ failure and are present in approximately half the cases of streptococcal toxic shock-like syndrome.[20]

Clostridial myonecrosis is a necrotizing infection that involves the skeletal muscle. Gas production and muscle necrosis are prominent features of this infection, which readily explains why this infection is commonly referred to as *gas gangrene.*[47,48] The infection advances rapidly, often over a matter of a few hours.[47,48] Most infections occur after surgery or trauma, with *Clostridium perfringens* identified as the most common etiologic agent.

CLINICAL PRESENTATION

General

- These infections may occur in almost any anatomic location but most frequently involve the abdomen, the perineum, and the lower extremities.
- Patients often have predisposing factors such as diabetes mellitus, local trauma or infection, or recent surgery.

Symptoms

- Systemic symptoms generally are marked (e.g., fever, chills, and leukocytosis) and may include shock and organ failure, especially for patients with type II infections.
- In general, pain in the affected area and systemic toxicity are more pronounced than would be expected with cellulitis.

Signs

- At the beginning of an infection, it may be difficult to differentiate between necrotizing fasciitis and cellulitis.
- Like cellulitis, the affected area is initially hot, swollen, and erythematous without sharp margins.
- The affected area is often shiny, exquisitely tender, and painful.
- Diffuse swelling of the area is followed by the appearance of bullae filled with clear fluid.
- The infectious process progresses rapidly, with the skin taking on a maroon or violaceous color after several days.
- Without appropriate intervention, the infection will evolve rapidly into a frank cutaneous gangrene, sometimes with myonecrosis (involvement of skin and muscle).
- Because of the aggressive nature and high mortality (20% to 50%) associated with these infections, a rapid diagnosis is critical.

Laboratory Tests

- Although computed tomography and magnetic resonance imaging studies can distinguish these infections, the best and most rapid diagnosis of necrotizing infections is obtained via surgical exploration.
- Intraoperative samples should be collected for culture and sensitivity, as well as for histologic examination.
- Unlike necrotizing fasciitis, clostridial myonecrosis shows little inflammation on histologic examination.

Other Diagnostic Tests

- Because marked systemic symptoms are seen commonly in necrotizing infections, blood samples should be collected for complete blood count and chemistry profile, as well as for bacterial culture.

TREATMENT

Necrotizing Soft-Tissue Infections

After the diagnosis is made, immediate and aggressive surgical debridement of all necrotic tissue is essential.[47–49] Initial surgical debridement performed greater than 14 hours after the diagnosis of necrotizing infection was independently associated with increased patient mortality, including a 34-fold increased risk of death for patients with septic shock.[50] Patients often require further surgical intervention following initial debridement to ensure that all necrotic tissue has been removed.[2,11,47–50] Broad-spectrum antibiotics must include coverage against streptococci, Enterobacteriaceae, and anaerobes. A number of antibiotic regimens have been used to successfully treat necrotizing soft-tissue infections; these are generally similar to those used for severe polymicrobic cellulitis involving anaerobes (see Table 119–5). Other combination antibiotic regimens that may be used empirically include ampicillin with gentamicin and clindamycin (or metronidazole), ampicillin-sulbactam with gentamicin, and imipenem with metronidazole.[19,47–49]

Antibiotic therapy can be modified after Gram stain and culture reports are available. If a diagnosis of type II necrotizing fasciitis is established, broad-spectrum empirical therapy should be replaced with the combination of penicillin and clindamycin.[20] Although *S. pyogenes* remains susceptible to penicillin, clindamycin is more effective.[20] A number of factors have been postulated to explain the greater efficacy of clindamycin, including the mechanism of action (inhibition of protein synthesis), which may cause decreased production of bacterial exotoxins.[20,47–49] In addition, clindamycin has immunomodulatory properties that may account for the higher efficacy.[20] The combination of penicillin and clindamycin is also recommended for treatment of clostridial myonecrosis.[11,47,48] Hyperbaric oxygen also may be of some benefit for clostridial myonecrosis.[47,48,51]

EVALUATION OF THERAPEUTIC OUTCOMES

Because of the high mortality associated with necrotizing infections, rapid and complete debridement of all devitalized and necrotic tissue is essential. Surgical debridement, coupled with appropriate antimicrobial therapy and supportive measures for management of shock and organ failure, should stabilize the patient. Vital signs and laboratory tests should be monitored carefully for signs of resolution of the infection. Change in antimicrobial therapy or additional surgical debridement may be needed for patients who do not show signs of improvement.

DIABETIC FOOT INFECTIONS

Three major types of foot infections are seen in diabetic patients: deep abscesses, cellulitis of the dorsum, and mal perforans ulcers.[52–55] Most deep abscesses involve the central plantar space (arch) and are caused by minor penetrating trauma or by an extension of infection of a nail or web space of the toes. Infections of the dorsal area generally arise from infections in the toes that are related to routine care of the nails, nail beds, and calluses of the toes. Mal perforans ulcer is a chronic ulcer of the sole of the foot. The ulcer develops on thickened, hardened calluses over the first or fifth metatarsal. Mal perforans ulcers are associated with neuropathy, which is responsible for the misalignment of the weight-bearing bones of the foot.[52–55] Osteomyelitis is one of the most serious complications of foot problems in diabetic patients and may occur in 30% to 40% of infections.[18,52–55]

EPIDEMIOLOGY

Infections of the foot are among the most common complications of diabetes, accounting for as many as 20% of all hospitalizations of diabetic patients at an annual cost of $200 to $350 million.[18,52–55] Approximately 25% of diabetic patients experience significant soft-tissue infection at some time during their lifetime. Approximately 55,000 lower-extremity amputations, often sequelae of uncontrolled infection, are performed each year on diabetic patients; this represents 50% of all nontraumatic amputations in the United States.[52–54] Between 10% and 20% of diabetics will undergo additional surgery or amputation of a second limb within 12 months of the initial amputation.[52–54] By 5 years, this increases to 25% to 50%, with death reported in as much as two thirds of patients.[52–54]

ETIOLOGY

Diabetic foot infections begin with local bacterial invasion and are typically polymicrobic in nature, with an average of 2.3 to 5.8 isolates per culture (Table 119–6).[18,52–59] Staphylococci (especially *S. aureus*) and streptococci are the most common pathogens, although gram-negative bacilli and/or anaerobes occur in approximately 50% of cases.[18,54–59] Common gram-negative isolates include *E. coli,*

TABLE 119-6 Bacterial Isolates from Foot Infections in Diabetic Patients

Organisms	Percentage of Isolates
Aerobes	63–75%
Gram-positive	42–64%
Staphylococcus aureus	15–20%
Streptococcus spp.	6–12%
Enterococcus spp.	7–20%
Coagulase-negative staphylococci	6–10%
Other gram-positive aerobes	0–12%
Gram-negative	16–18%
Proteus spp.	5–6%
Enterobacter spp.	1–2%
Escherichia coli	3–5%
Klebsiella spp.	1–2%
Pseudomonas aeruginosa	1–3%
Other gram-negative bacilli	3–8%
Anaerobes	25–40%
Peptostreptococcus spp.	8–12%
Bacteroides fragilis group	4–7%
Other *Bacteroides* spp.	3–6%
Clostridium spp.	0–2%
Other anaerobes	7–10%

Compiled from references 18, 62, 65.

Klebsiella spp., *Proteus* spp., and *P. aeruginosa. Bacteroides fragilis* and *Peptostreptococcus* spp. are among the most common anaerobes isolated. Methicillin-resistant *S. aureus* has been reported in up to 30% of diabetic foot wounds.[60] However, whether MRSA is associated with worse patient outcomes is still somewhat controversial, and the clinical relevance of MRSA in this setting is not clear.[57]

The optimum technique for obtaining culture material from ulcerated lesions is still debated.[52–56] Routine swab cultures of ulcerative lesions or sinus tracts are difficult to interpret because of organisms that colonize the wounds. The correlation between superficial cultures and true deep cultures (via biopsy or needle aspiration of drainage or abscess fluid) is often poor, particularly in chronic lesions.[18,54–56] Therefore, cultures and sensitivity tests should be done with specimens obtained from a deep culture whenever possible. Before the wound is cultured, it should be scrubbed vigorously with saline-moistened sterile gauze to remove any overlying necrotic debris.[18,54–56] Cultures then can be obtained from the wound base, preferably from expressed pus.[54–56] Specimens obtained from curettage of the base of the ulcer correlate best with results from deep-tissue or bone biopsies.[61–63]

PATHOPHYSIOLOGY

Three key factors are involved in the development of diabetic foot problems:

1. Neuropathy
2. Angiopathy and ischemia
3. Immunologic defects

Any of these disorders can occur in isolation; however, they frequently occur together.

Neuropathic changes to the autonomic nervous system as a consequence of diabetes may affect the motor nerve supply of small intrinsic muscles of the foot, resulting in muscular imbalance, abnormal stresses on tissues and bone, and repetitive injuries.[52–54] Diminished sensory perception causes an absence of pain and unawareness of minor injuries and ulceration. The sympathetic nerve supply may be damaged, resulting in an absence of sweating, which may lead to dry cracked skin and secondary infection.[18,52–54]

Atherosclerosis is more common, appears at a younger age, and progresses more rapidly in the diabetic than in the nondiabetic. Diabetics may have problems with both small vessels (microangiopathy) and large vessels (macroangiopathy) that can result in varying degrees of ischemia, ultimately leading to skin breakdown and infection.

Diabetic patients typically have normal humoral immunity, normal levels of immunoglobulins, and normal antibody responses. Patients with diabetes, however, have impaired phagocytosis and intracellular microbicidal function as compared with nondiabetics; this may be related to angiopathy and low tissue levels of oxygen.[18,52,53] These defects in cell-mediated immunity make patients with diabetes more susceptible to certain types of infection and impair the patients' ability to heal wounds adequately.[52–54,57]

CLINICAL PRESENTATION

General

- Infections are often much more extensive than they appear initially.

Symptoms

- Patients with peripheral neuropathy often do not experience pain but seek medical care for swelling or erythema in the foot.

Signs

- Clinical signs of infection in the diabetic foot may not be present secondary to the angiopathy and neuropathy.
- When present, lesions vary in size and clinical features (e.g., erythema, edema, warmth, presence of pus, draining sinuses, pain, and tenderness).
- A foul-smelling odor suggests the presence of anaerobic organisms.
- Temperature may be mildly elevated or normal.

Laboratory Tests

- Specimens for culture and sensitivities should be collected.
- If possible, deep intraoperative samples should be obtained during surgical debridement.
- Because of the complex microbiology of these infections, wounds must be cultured for both aerobic and anaerobic organisms.

Other Diagnostic Tests

- The presence of osteomyelitis also must be assessed via radiograph, bone scan, or both, as appropriate.

TREATMENT

Diabetic Foot Infections

7 The goal of therapy of diabetic foot infections is preservation of as much normal limb function as possible while preventing additional infectious complications. Up to 90% of infections can be treated successfully with a comprehensive treatment approach that includes both wound care and antimicrobial therapy.[18,57–59] After carefully assessing the extent of the lesion and obtaining necessary cultures, necrotic tissue must be thoroughly debrided, with wound drainage and amputation as required. Wounds must be kept clean and dressings changed frequently (two to three times daily). Because of the relationship between hyperglycemia and immune system defects, glycemic control must be maximized to ensure optimal wound healing. In addition, the patient's activities should be restricted initially to bedrest for leg elevation and control of edema, if present. Adequate pressure relief from a foot wound (i.e., off-loading) is crucial to the healing process.[18,64] Finally, appropriate antimicrobials must be initiated.[18,54–59] However, the optimal antimicrobial therapy for diabetic foot infections has yet to be defined. Empirical therapy that is totally comprehensive in its coverage of all possible pathogens does not seem to be necessary unless the infection is life or limb threatening.[18,57–59] This is particularly true regarding MRSA and *P. aeruginosa*, the perceived need for coverage of these organisms often leading to use of broad-spectrum drug regimens. One comparative study showed good efficacy rates despite that fact that neither agent (ertapenem and piperacillin-tazobactam) had consistently good activity against these organisms.[65]

The majority of mild, uncomplicated infections can be managed successfully on an outpatient basis with oral antimicrobials and good wound care. Many different agents have been studied, including cephalosporins, fluoroquinolones, clindamycin, and amoxicillin-clavulanic acid, and provide clinical cure rates of 60% to 85%.[18,54–59] However, significant failure and/or relapse rates have been reported with the use of oral agents. In addition, the development of resistance was problematic in some infections involving *P. aeruginosa* and staphylococci.[18,57] Many clinicians consider amoxicillin-clavulanic acid to be the preferred agent because of its broad spectrum of activity, which includes staphylococci, streptococci,

enterococci, and many Enterobacteriaceae and anaerobes.[18,57–59] However, this agent does not have activity against *P. aeruginosa.* Fluoroquinolones, which provide coverage against *P. aeruginosa,* have been studied extensively as monotherapy but are perhaps most appropriately used in combination with metronidazole or clindamycin to provide anaerobic activity.[2,18,57] Oral antimicrobials should be used cautiously in serious infections, especially those complicated by osteomyelitis, extensive ulceration, areas of necrosis, or a combination of these. The use of topical antimicrobials, including medical-grade honey, has been advocated for the treatment of diabetic foot infections in an attempt to minimize the cost of therapy and systemic antibiotic exposure leading to adverse effects and resistance. However, use of topical agents is quite controversial and not routinely recommended outside of the treatment of infected burn wounds.[66,67]

Initial therapy for patients requiring hospitalization for moderate to severe infections is similar to that for polymicrobic cellulitis with anaerobes (see Table 119–5). Monotherapy with broad-spectrum parenteral antimicrobials, along with appropriate medical or surgical management, or both, is often effective in treating these infections, including those in which osteomyelitis is present.[18,57–59,63] Monotherapy is particularly attractive because of the potential advantages of convenience, cost, and avoidance of toxicities. Microbiological and clinical cure rates ranging from 60% to 90% may be expected from any of these agents; selection of a specific regimen is determined primarily by cost. In penicillin-allergic patients, metronidazole or clindamycin plus either a fluoroquinolone, aztreonam or possibly a third-generation cephalosporin is appropriate.[2,18,57–59] Vancomycin also is used frequently in severe infections because of its excellent activity against gram-positive pathogens. With the increased incidence of MRSA, linezolid, quinupristin-dalfopristin, daptomycin, and tigecycline are alternatives for treatment of this pathogen.[1,2,18,57–59] Tigecycline may be particularly useful in this setting because of its activity against gram-negative aerobes and anaerobic bacteria, thus allowing it to be used as monotherapy for the treatment of mixed infections. Because many patients already have some degree of diabetic nephropathy that may place them at higher risk of nephrotoxicity, strong recommendations have been made against the use of aminoglycoside antibiotics unless no alternative agents are available.[18,57] When an aminoglycoside is used, care must be taken to avoid further compromising renal function. All antibiotic regimens should be adjusted as necessary for renal dysfunction.

Mild to moderate infections can be treated with highly bioavailable oral agents. Duration of therapy is usually 7 to 14 days, although some infections may require an additional 1 to 2 weeks of therapy. More severe infections require initial parenteral therapy. Duration of therapy for most moderate to severe infections ranges from 2 to 4 weeks.[18,57] In cases of underlying osteomyelitis, treatment should continue for 6 to 12 weeks.[18,57–59,63] After healing of the infection has occurred, a well-designed program for prevention of further infections should be instituted. The use of adjunctive agents such as colony stimulating factors and hyperbaric oxygen for either prevention or treatment of diabetic foot infections are controversial and not widely recommended.[68,69]

EVALUATION OF THERAPEUTIC OUTCOMES

Therapy should be reevaluated carefully after 48 to 72 hours to assess favorable response. Change in therapy (or route of administration, if oral) should be considered if clinical improvement is not observed at this time. For optimal results, drug therapy should be appropriately modified according to information from deep-tissue culture and the clinical condition of the patient. Infections in diabetic patients often require extended courses of therapy because of impaired host immunity and poor wound healing.

TABLE 119-7 Pressure Sore Classification

Suspected deep tissue injury	Area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. Area may be preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler as compared with adjacent tissue.
Stage 1	Pressure sore is generally reversible, is limited to the epidermis, and resembles an abrasion. Intact skin with nonblanchable redness of a localized area, usually over a bony prominence. The area may be painful, firm, soft, warmer, or cooler as compared with adjacent tissue.
Stage 2	A stage 2 sore also may be reversible; partial thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed. May also present as an intact or open/ruptured serum-filled blister or as a shiny or dry shallow ulcer.
Stage 3[a]	Full thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon, or muscles are not exposed. May include undermining and tunneling. Depth of the ulcer varies by anatomical location; may range from shallow to extremely deep over areas of significant adiposity.
Stage 4[a]	Full thickness tissue loss with exposed bone, tendon, or muscle; can extend into muscle and/or supporting structures (e.g., fascia, tendon, or joint capsule) making osteomyelitis possible. Often include undermining and tunneling; depth of the ulcer varies by anatomical location.
Unstageable[a]	Full thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed. True depth, and therefore stage, cannot be determined.

[a]Stage 3, Stage 4, and unstageable lesions are unlikely to resolve on their own and often require surgical intervention.

From reference 70.

PRESSURE SORES

The terms *decubitus ulcer, bed sore,* and *pressure sore* are used interchangeably. The decubitus ulcer and the bed sore are types of pressure sores. The term *decubitus ulcer* is derived from the Latin word *decumbere,* meaning "lying down." Pressure sores, however, can develop regardless of a patient's position.

Numerous systems for classification of pressure sores have been described. The 2007 recommendations of the National Pressure Ulcer Advisory Panel are shown in Table 119–7 and illustrate the various stages of progression through which a pressure sore may pass.[70]

Complications of pressure sores are not uncommon and may be life threatening. Infection is one of the most serious and most frequently encountered complications of pressure ulcers. Bacterial colonization must be differentiated from true bacterial infection. Although most pressure sore wounds are colonized, the majority of these eventually heal.[71–75] When the tissue is infected, there is bacterial invasion of previously healthy tissue. Without treatment, an initial small, localized area of ulceration can rapidly progress to large ulcers within days. The visible ulcer is just a small portion of the actual wound; up to 70% of the total wound is below the skin. A pressure-gradient phenomenon is created by which the wound takes on a conical nature; the smallest point is at the skin surface, and the largest portion of the defect is at the base of the ulcer (Fig. 119–1).

EPIDEMIOLOGY

Pressure sores are most common among chronically debilitated persons, the elderly, and persons with serious spinal cord injury.

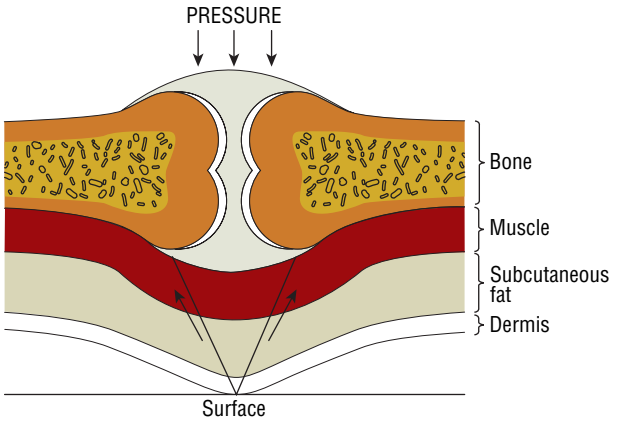

FIGURE 119-1. Distribution of forces involved with sore formation in a conical fashion.

Generally, patients who are at risk for pressure sores are elderly or chronically ill young patients who are immobilized, either in bed or a wheelchair, and who may have altered mental status and/or incontinence.

ETIOLOGY

Similar to diabetic foot infections, a large variety of aerobic gram-positive and gram-negative organisms, as well as anaerobes, frequently are isolated from wound cultures.[73] Curettage of the ulcer base after debridement provides more reliable culture information than does needle aspiration.[71–75] Biopsy specimens give the most reliable data but may not be practical to obtain. Deep-tissue cultures from different sites may give different results. Cultures collected from pressure ulcers reveal polymicrobial growth. A culture collected by swab is likely to identify surface bacteria colonizing the wound rather than to diagnose the infection.[71–75]

PATHOPHYSIOLOGY

Many factors apparently predispose patients to the formation of pressure sores: paralysis, paresis, immobilization, malnutrition, anemia, infection, and advanced age. Factors thought to be most critical to their formation are pressure, shearing forces, friction, and moisture; however, there is still debate as to the exact pathophysiology of pressure sore formation.

Pressure is the essential element in the formation of pressure sores. The areas of highest pressure are generated most often over the bony prominences. When the pressure is relieved intermittently within a 2-hour period, only minimal changes occur in soft-tissue and skin structures.[71,72] Therefore, both the degree of pressure and the length of time that the pressure is applied are important.

Shearing forces are caused by the sliding of adjacent parallel surfaces of soft tissues in an unequal fashion. This situation can occur when the head of a bed is raised, causing the upper torso to slide downward, transmitting pressure to the sacrum and other areas. This effect results in occlusion or distortion of vessels, leading to compromise of the dermis. At the same time, sitting and gravity create shearing forces; the posterior sacral skin area can become fixed secondary to friction with the bed. The effects of friction and shearing forces combine, resulting in transmission of force to the deep portion of the superficial fascia and leading to further damage of soft-tissue structures.[71–75]

Compounding the problems of shearing and friction forces are the macerating effects of excessive moisture in the local environment, resulting from incontinence and perspiration. This factor is of critical importance because when combined with the other forces, it increases the risk of pressure sore formation fivefold.[71,72]

CLINICAL PRESENTATION

General

- Pressure sores can occur anywhere on the body.
- However, more than 95% of all pressure sores are located on the lower part of the body (65% in the region of the pelvis and 3.4% on the lower extremities; see Fig. 119–2).
- The most common sites on the lower portion of the body are the sacral and coccygeal areas, ischial tuberosities, and greater trochanter.

Symptoms

- Patients with pressure sores commonly have other medical problems that may mask the typical signs and symptoms of infection.

Signs

- Clinical infection is recognized by the presence of surrounding redness, heat, and pain.
- Purulent discharge, foul odor, and systemic signs (e.g., fever and leukocytosis) of infection may be present.

Laboratory Tests

- Cultures should be collected from either a biopsy or fluid obtained by needle aspiration.

Other Diagnostic Tests

- Because clinicians also must be aware of the possibility of underlying osteomyelitis, magnetic resonance imaging or other radiographic procedures should be considered.

TREATMENT

Pressure Sores

8 Prevention is the single most important aspect in the management of pressure sores. Prevention is far easier and less costly than the intensive care necessary for the healing and eventual closure of pressure sores. Of primary importance, then, is the ability to identify patients who are at high risk so that preventive measures may be instituted.

The medical approach to the treatment of pressure sores depends on the stage of the disease. Medical management generally is indicated for lesions that are of moderate size and relatively shallow depth (stage 1 or 2 lesions) and are not located over a bony prominence. Depending on their location and severity, from 30% to 80% of these ulcers will heal without an operation. Surgical intervention is almost always necessary for ulcers that extend through superficial layers or into bone (stage 3, stage 4 and unstageable lesions).[70,71]

The goal of therapy is to clean and decontaminate the ulcer to promote wound healing by permitting the formation of healthy granulation tissue or to prepare the wound for an operative procedure. The main factors to be considered for successful topical therapy (local care) are (a) relief of pressure, (b) debridement of necrotic tissue as needed, (c) wound cleansing, (d) dressing selection, and (e) prevention, diagnosis, and treatment of infection.[71–75]

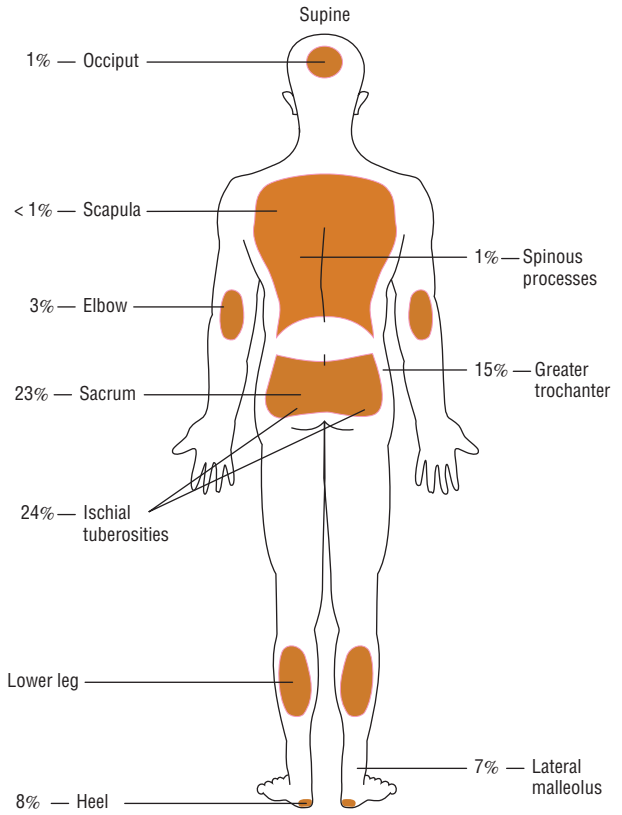

FIGURE 119-2. Supine view of areas where pressure sore formation tends to occur.

Friction and shearing forces can be minimized with proper positioning. Skin care and prevention of soilage are important, with the intent being to keep the surface relatively free of moisture. Patients with problems of incontinence should be cleaned frequently, and efforts should be made to keep the involved areas dry. Natural sheepskin is believed to be useful in minimizing the effects of moisture, shearing forces, and friction. Relief of pressure is probably the single most important factor in preventing pressure sore formation. Relief for a period of only 5 minutes once every 2 hours is believed to give protection against pressure sore formation.[71–75]

The goals of debridement and cleansing measures are removal of devitalized tissue and reduction of bacterial contamination, which can slow granulation time and, therefore, impede healing. Debridement can be accomplished by surgical, mechanical, or chemical means. Surgical debridement rapidly removes necrotic material from the wound and is recommended for urgent situations (e.g., cellulitis and sepsis).[71–75] Mechanical debridement generally involves wet-to-dry dressing changes. Saline-soaked gauze is applied to the wound; after drying, the gauze is removed and with it any adherent necrotic tissue. Other effective mechanical therapies include hydro-therapy (use of the whirlpool [Hubbard tank] to remove necrotic tissue and debris), wound irrigation, and dextranomers (beads placed in the wound to absorb exudate and bacteria). Chemical debridement includes enzymatic and autolytic agents. Enzymatic debridement involves application of topical debriding agents to remove devitalized tissue. This method is recommended for patients who cannot tolerate surgery or are in a long-term care or home setting. Autolytic debridement involves the use of synthetic dressings that allow devitalized tissue to self-digest via enzymes present in wound fluids. Autolytic debridement is contraindicated in the treatment of infected pressure sores.

Pressure sore wounds should be cleaned with normal saline. Cleansing agents that are cytotoxic, such as povidone-iodine, iodophor, sodium hypochlorite solution, hydrogen peroxide, and acetic acid, should be avoided.[71–75] Many of these agents impair healing. Many different types of dressings are available for pressure sores. Wound dressing materials should keep the wound moist, allow free exchange of air, act as a physical barrier to bacteria, and prevent physical damage. Controlled studies of the various types of wound dressings have shown no significant differences in healing outcomes.[71] Occlusive dressings should be avoided if infection is present.[71–75] If occlusive dressings are used, any infection should be controlled or the dressing frequency increased.

Systemic treatment (see Table 119–5) of an infected pressure ulcer should be guided by results from appropriately collected cultures. Systemic antibiotics generally are reserved for treatment of bacteremia, sepsis, cellulitis, or osteomyelitis.[71–75] However, a 2-week trial of topical antibiotics (silver sulfadiazine or triple antibiotic) may be considered for a clean ulcer that is not healing or is producing a moderate amount of exudate despite appropriate care.[71]

Other nonpharmacologic approaches to shortening the healing time have included the use of hyperbaric oxygenation, hydrotherapy, high-frequency/high-intensity sound waves, and electrotherapy.[71–75] Electrical stimulation is the only adjunctive therapy that is proven effective.[71–75]

EVALUATION OF THERAPEUTIC OUTCOMES

With appropriate wound care and antimicrobial therapy, infected pressure sores can heal. A reduction in erythema, warmth, pain, and other signs and symptoms should be seen in 48 to 72 hours.

BITE WOUNDS

Approximately half the population in the United States will be bitten by either an animal or another human sometime during their lifetimes.[76] Bite wounds have a substantial potential for infectious complications. If left untreated, complications such as soft-tissue infection and osteomyelitis may occur, possibly requiring extensive débridement or amputation.

ANIMAL BITES

Animal bites (typically from dogs or cats) are common causes of injury, particularly to children, and are associated with significant risk of infection without prompt attention to appropriate management.

Epidemiology

Dog bites account for approximately 80% of all animal bite wounds requiring medical attention. Data from U.S. emergency departments reported 368,245 visits for new dog bite-related injuries in 2001.[76] Based on this study, approximately 1,000 new dog bite injuries are seen in emergency departments every day. Approximately one half of dog bites occur in individuals younger than 20 years of age, usually males (55%). More than 70% of bites are to the extremities. Facial bites are also seen, particularly in children younger than 5 years of age. Up to 65% of bite wounds in young children involve the head and neck, and can be a lethal event because of blood loss. From 1979 through 1994, 279 deaths were the result of attacks by dogs.[77]

Patients at greatest risk of acquiring a bite-related infection have had a puncture wound (usually the hand), have not sought medical

attention within 12 hours of the injury, and are older than 50 years of age.[78,79]

Cat bites, with an estimated incidence of 5% to 15% of all animal bites, are the second most common cause of animal bite wounds in the United States.[78] Bites and scratches occur most commonly on the upper extremities, with most injuries reported in women.[78] Infection rates, estimated at 30% to 50%, are more than double those seen with dog bites.[78,79]

Etiology

Infections from dog bite wounds are caused predominantly by mouth flora from the animal.[80–82] Most infections are polymicrobial, with approximately five bacterial isolates per culture.[80–82] *Pasteurella multocida* is the most frequent isolate. Other common aerobes include streptococci, staphylococci, *Moraxella,* and *Neisseria.* The most common anaerobes are *Fusobacterium, Bacteroides, Porphyromonas,* and *Prevotella.*[80–82] Wound-site cultures in both infected and noninfected patients have similar bacteria present, with aerobic organisms isolated from 74% to 90% and anaerobic organisms isolated from 41% to 49% of patients.[78,80]

Infections arising from cat bites or scratches are frequently (75%) caused by *P. multocida,* which has been isolated in the oropharynx of 50% to 70% of healthy cats.[78,82] Mixed aerobic and anaerobic infections have been reported in 63% of cat bite wounds, whereas approximately one third of cultures grow aerobes only.[78,82] Both tularemia (*Pasteurella tularensis*) and rabies also have been transmitted by cat bites.[78,82]

Pathophysiology

The potential for infection from an animal bite is great owing to the pressure that can be exerted during the bite and the vast number of potential pathogens that make up the normal oral flora.[81] Cats' teeth are slender and extremely sharp. Their teeth easily penetrate into bones and joints, resulting in a higher incidence of septic arthritis and osteomyelitis.[78] Although a dog's teeth may not be as sharp, they can exert a pressure of 200 to 450 lb/in^2 and therefore result in a serious crush injury with much devitalized tissue.[81] Known human pathogens such as *S. aureus*, *P. multocida*, and anaerobes are among the more than 64 species of bacteria that are harbored in the average dog mouth.[81] In addition, the polymicrobic (aerobic and anaerobic) nature of animal bites provides a synergistic relationship, thus making an infection harder to eradicate.[81]

CLINICAL PRESENTATION

General

- Healthcare providers see two distinct groups of patients seeking medical attention for dog bites.
- The first group presents within 12 hours of the injury; these patients require general wound care, repair of tear wounds, or rabies and/or tetanus treatment. The second group of patients presents more than 12 hours after the injury has occurred; these patients usually have clinical signs of infection and seek medical attention for infection-related complaints.

Symptoms

- Patients seek medical care for infection-related complaints (i.e., pain, purulent discharge, and swelling).

Signs

- Patients with infected dog bite wounds generally present with a localized cellulitis and pain at the site of injury.
- Cellulitis usually spreads proximally from the initial site of injury, and a gray malodorous discharge may be encountered.
- If *P. multocida* is present, a rapidly progressing cellulitis is observed, with pain and swelling developing within 24 (70%) to 48 (90%) hours of initial injury.
- Fever is uncommon.
- Fewer than 20% of patients have a concomitant adenopathy or lymphangitis.

Laboratory Tests

- Samples for bacterial cultures (aerobic and anaerobic) should be obtained.
- Wounds seen less than 8 hours or more than 24 hours after injury that show no signs of infection may not need to be cultured.

Other Diagnostic Tests

- A roentgenogram of the affected part should be considered when infection is documented in proximity to a bone or joint.

TREATMENT

Dog and Cat Bites

Table 119–4 lists the recommended drugs and dosing regimens for animal bite wounds.

Cultures obtained from early, noninfected bite wounds are not of great value in predicting the subsequent development of infection. Documentation of the mechanism of injury is important; if possible, an immunization history of the animal should be obtained. It is also important for the patient's tetanus immune status to be determined.

Wounds should be irrigated thoroughly with a copious volume (>150 mL) of sterile normal saline. Proper irrigation reduces the bacterial count in the wound. Antibiotic or iodine solutions do not offer any advantage over saline and actually may increase tissue irritation. Several management techniques used in the treatment of bite wounds remain controversial, including the extent and type of debridement,[78,83,84] suturing wounds within 8 hours of the injury,[11] and indications for the use of antibiotics.

The role of prophylactic antimicrobial therapy for the early, noninfected bite wound remains controversial.[78,82,85,86] Unfortunately, suggestions concerning the use of prophylactic antibiotics are based on minimal data because few clinical trials have been performed. Most reports are of retrospective studies or observations of complicated cases. A systematic review of eight randomized trials of bite wounds (caused by both animals and humans) evaluated the use of antibiotics for the prevention of infectious complications and concluded that antibiotics did not significantly reduce the risk of infection for patients with dog or cat bites but that wounds involving the hands may benefit from antimicrobial prophylaxis.[86] However, this review also concluded that additional studies are required to support these conclusions.[86]

Controlled studies have not shown benefits definitively with prophylactic antibiotics for noninfected bites. Because up to 20% of bite wounds may become infected, a 3- to 5-day course of antimicrobial therapy generally is recommended.[11,78,82] This is especially important for patients at greater risk for infection (patients older than 50 years of age and those with puncture wounds and wounds to the hands, and those who are immunocompromised).[82,85]

Treatment should be directed at the typical aerobic and anaerobic oral flora of dogs, as well as at potential pathogens from the skin flora of the bite victim. The length of antimicrobial therapy depends on the severity of the injury/infection.[11,78] Amoxicillin-clavulanic acid is commonly recommended for oral outpatient therapy.[11,78,82] Alternative oral agents include doxycycline or the combination of penicillin VK and dicloxacillin. Trimethoprim-sulfamethoxazole and fluoroquinolones have activity against *P. multocida* and are recommended as alternatives for patients who are allergic to penicillins.[11,78] However, these agents should not be used in children and/or pregnant women; trimethoprim-sulfamethoxazole also should be avoided during pregnancy. Macrolides or azalides may be considered as alternatives for growing children or pregnant women.[11,78,83] If erythromycin or similar-class agent is selected, bacterial sensitivities should be obtained and clinical response monitored carefully because most strains of *P. multocida* are resistant. Cefuroxime is another viable alternative for patients with mild penicillin allergies. Many of these alternative agents will likely require an additional agent (metronidazole, clindamycin) with activity against anaerobes. Failure to provide adequate initial treatment of bite wounds results in treatment failures and increased need for hospitalization for administration of parenteral antibiotics.[87]

Treatment options for patients requiring intravenous therapy include β-lactam–β-lactamase inhibitor combinations (ampicillin-sulbactam, piperacillin-tazobactam), second-generation cephalosporins with antianaerobic activity (cefoxitin), and carbapenems.[11,78,82]

In addition to irrigation and antibiotics, when indicated, the injured area should be immobilized and elevated. Clinical failures due to edema have occurred despite appropriate antibiotic therapy.[78] Therefore, it is important to stress to patients that the affected area should be elevated for several days or until edema has resolved.

Tetanus does not occur commonly after dog bites; however, it is possible. If the immunization history of a patient with anything other than a clean, minor wound is unknown, tetanus-diphtheria (TD) toxoids should be administered (0.5 mL intramuscularly).[88] Both TD toxoids and tetanus immune globulin (250 units intramuscularly) should be administered to patients who have never been immunized.[82,89]

Because the rabies virus can be transmitted via saliva, rabies may be a potential complication of a bite. When the symptoms of rabies develop after a bite, the prognosis for survival is poor. Roughly 3% of rabies cases documented in animals were in dogs (the most frequent vectors are skunks, raccoons, and bats).[90]

After a patient has been exposed to rabies, the treatment objectives consist of thorough irrigation of the wound, tetanus prophylaxis, antibiotic prophylaxis, if indicated, and immunization. Prompt, thorough irrigation of the wound with soap or iodine solution may reduce the development of rabies.[90] Postexposure prophylaxis immunization against rabies consists of the administration of both passive antibody and vaccine.[89,90] The vaccine is administered as a series of five 1 mL intramuscular injections given on days 0, 3, 7, 14, and 28, beginning on the day of exposure or as soon as possible afterward. Rabies hyperimmune globulin is administered at a dose of 40 international units/kg; as much of the total dose as possible should be infiltrated into and around the wound, with the remainder being injected intramuscularly at a site different from that of the vaccine.[89] The only exceptions to administration of hyperimmune globulin are patients who were immunized previously and who have the appropriate degree of documented rabies antibody titers. However, even individuals who have been fully vaccinated should receive two doses of vaccine on days 0 and 3 after actual rabies exposure.[89,90]

The management of cat bites is similar to that discussed for dog bites. Cat scratches typically involve the same organisms as bites and should be treated accordingly.

Evaluation of therapeutic outcomes

Bite victims treated on an outpatient basis with oral antimicrobials should be followed up within 24 hours either by phone or office visit.[11] Hospitalization or change to intravenous therapy should be considered if the infection has progressed. For hospitalized patients with no improvement in signs and symptoms following 24 hours of appropriate therapy, then surgical debridement may be needed.

HUMAN BITES

Human bite wounds are often deceptively severe and frequently require aggressive management to reduce the risk of infectious complications.

Epidemiology

Human bites are the third most frequent type of bite. Infected human bites can occur as bites from the teeth or from blows to the mouth (clenched-fist injuries). Human bites generally are more serious than animal bites and carry a higher likelihood of infection than do most animal bites. Infectious complications occur in 10% to 50% of patients with human bites.[78,91]

Self-inflicted bites most commonly occur on the lips or around the fingernails (from sucking or biting the nails). Bites by others can occur to any part of the body but most often involve the hands. Bites to the hand are most serious and become infected more frequently. The clenched-fist injury is a traumatic laceration caused by one person hitting another in the mouth and is a very serious bite wound. The areas most commonly affected by this injury are the third and fourth metacarpophalangeal joints.[92]

Etiology

Infections caused by these injuries are similar and are caused most often by the normal oral flora, which include both aerobic and anaerobic microorganisms. *Streptococcus* spp. (especially *Streptococcus anginosus*) are the most common isolates, followed by *Staphylococcus* spp. (predominately *S. aureus*).[93] *Eikenella corrodens* is isolated from human bite wounds approximately 30% of the time.[78,93] Anaerobic microorganisms have been isolated in approximately 40% of human bites and 55% of clenched-fist injuries. Common anaerobes recovered from human bite infections include *Fusobacterium*, *Prevotella*, *Porphyromonas,* and *Peptostreptococcus* species.[93]

Pathophysiology

Human bites generally are more serious and more prone to infection than animal bites, particularly clenched-fist injuries.[81] While the force of a punch may sever a tendon or nerve or break a bone, it most often causes a breach in the capsule of the metacarpophalangeal joint, leading to direct inoculation of bacteria into the joint or bone.[78] When the hand is relaxed, the tendons carry bacteria into deeper spaces of the hand, resulting in more extensive infection.[78]

CLINICAL PRESENTATION

General

- Most clenched-fist injuries are already infected by the time patients seek medical care, and most require hospitalization.

Symptoms

- Patients with infected bites to the hand may develop a painful, throbbing, swollen extremity.
- Wounds often have a purulent discharge, and the patient complains of a decreased range of motion.

Signs

- Signs of infection include erythema, swelling, and clear or pussy discharge.
- Adjacent lymph nodes may be enlarged.
- In clenched-fist injuries, edema may limit the ability of tendons to glide in their sheaths, thereby limiting a joint's range of motion.

Laboratory Tests

- Samples for bacterial cultures (aerobic and anaerobic) should be collected as per animal bites.
- In severe infections, a peripheral leukocytosis of 15,000 to 30,000 cells/mm^3 may be seen; therefore, the white blood count should be monitored for resolution of infection.

Other Diagnostic Tests

- If damage to a bone or joint is suspected, radiographic evaluation should be undertaken.

TREATMENT

Human Bites

Table 119–4 lists the recommended drugs and dosing regimens for human bite wounds.

9 Management of bite wounds consists of aggressive irrigation and topical wound cleansing. Surgical debridement and immobilization of the affected area is often required. Prophylactic antimicrobial agents should be given as soon as possible to all patients, regardless of the appearance of the wound, unless it can be documented that the wound does not involve hands, feet, or joints and penetrates no deeper than the epidermis.[11,79,82] Patients with clenched-fist injuries should be seen by a specialist in hand care to evaluate for penetration into the synovium, joint capsule, and bone.[11,78] Primary closure for human bites generally is not recommended. Tetanus toxoid and antitoxin may be indicated. Because transmission of viruses (HIV, herpes, hepatitides B and C) is a possibility with human bites, information about the biter is important. Although the possibility of acquiring HIV through bites is believed to be unlikely, the presence of the virus in the saliva makes disease transmission possible.[94] If the biter is HIV positive, the victim should have a baseline blood specimen drawn to determine preexposure HIV status and then be retested in 3 months and 6 months.[82,91,94] The bite wound should be irrigated thoroughly and vigorously with a virucidal agent such as povidone-iodine.[78] Bite victims exposed to blood-tainted saliva may be offered antiretroviral chemoprophylaxis, but each case should be individually assessed based on the potential for significant exposure and potential risks and benefits of antiretroviral therapy.[94]

10 Patients with human bite injuries should receive prophylactic antibiotic therapy for 3 to 5 days.[82,91,95] First-generation cephalosporins, macrolides, clindamycin, and aminoglycosides are not recommended because the sensitivity of these agents to *E. corrodens* is variable.[78,85,95]

Hospitalization for minor wounds is unnecessary if surgical repair of vital structures has not been performed. Patients suffering serious injuries or clenched-fist injuries should be started on intravenous antibiotics. Recommended agents include cefoxitin (1 g IV every 6 to 8 hours), ampicillin-sulbactam (1.5 to 3 g IV every 6 hours), or ertapenem (1 g IV every 24 hours).[11] Therapeutic failures have been documented when either first-generation cephalosporins or penicillinase-resistant penicillins have been used alone, most likely because of their poor and variable activity against *E. corrodens*. Therapy should be continued from 7 to 14 days.[11,91]

Evaluation of Therapeutic Outcomes

Evaluation of treatment should follow the same general guidelines as discussed for animal bite wounds. Complications with clenched-fist injuries are common and may result in residual joint stiffness and loss of function. Physical therapy can be needed to improve these complications.

ABBREVIATIONS

HIV: human immunodeficiency virus

MRSA: methicillin-resistant *Staphylococcus aureus*

CA-MRSA: community-associated methicillin-resistant *S. aureus*

SSTI: skin and soft-tissue infection

TD: tetanus-diphtheria

CHAPTER 120

Infective Endocarditis

ANGIE VEVERKA AND MICHAEL A. CROUCH

KEY CONCEPTS

1. Infective endocarditis is an uncommon infection usually occurring in persons with preexisting cardiac valvular abnormalities (e.g., prosthetic heart valves) or with other specific risk factors (e.g., intravenous drug abuse).
2. Three groups of organisms cause a majority of infective endocarditis cases: streptococci, staphylococci, and enterococci.
3. The clinical presentation of infective endocarditis is highly variable and nonspecific, although a fever and murmur usually are present. Classic peripheral manifestations (e.g., Osler nodes) may or may not occur.
4. The diagnosis of infective endocarditis requires the integration of clinical, laboratory, and echocardiographic findings. The two major diagnostic criteria are bacteremia and echocardiographic changes (e.g., valvular vegetation).
5. Treatment of infective endocarditis involves isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by high-dose, parenteral, bactericidal antibiotics for an extended period.
6. Surgical replacement of the infected heart valve is an important adjunct to endocarditis treatment in certain situations (e.g., patients with acute heart failure).
7. β-Lactam antibiotics, such as penicillin G (or ceftriaxone), nafcillin, and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal endocarditis, respectively.
8. Aminoglycoside antibiotics are essential to obtain a synergistic bactericidal effect in the treatment of enterococcal endocarditis. Adjunctive aminoglycosides also may decrease the emergence of resistant organisms (e.g., prosthetic valve endocarditis caused by coagulase-negative staphylococci) and hasten the pace of clinical and microbiologic response (e.g., some streptococcal and staphylococcal infections).
9. Vancomycin is reserved for patients with immediate β-lactam allergies and the treatment of resistant organisms.
10. Antimicrobial prophylaxis is used as an attempt to prevent infective endocarditis for patients who are at the highest risk (such as persons with prosthetic heart valves) before a bacteremia-causing procedure (e.g., dental extraction).

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Endocarditis is an inflammation of the endocardium, the membrane lining the chambers of the heart and covering the cusps of the heart valves.[1,2] More commonly, *endocarditis* refers to infection of the heart valves by various microorganisms. Although it typically affects native valves, it also may involve nonvalvular areas or implanted mechanical devices (e.g., mechanical heart valves). Bacteria primarily cause endocarditis, but fungi and other atypical microorganisms can lead to the disease; hence, the more encompassing term *infective endocarditis* is preferred.[2,3]

Endocarditis is often referred to as *acute* or *subacute* depending on the pace and severity of the clinical presentation. The acute, fulminating form is associated with high fevers and systemic toxicity. Virulent bacteria, such as *Staphylococcus aureus*, frequently cause this syndrome, and if untreated, death may occur within days to weeks. On the other hand, subacute infective endocarditis is more indolent, and it is caused by less-invasive organisms, such as viridans streptococci, usually occurring in preexisting valvular heart disease. Although infective endocarditis is often referred to as acute or subacute, it is best classified based on the etiologic organism, the anatomic site of infection, and pathogenic risk factors.[1,4,5] Infection also may follow surgical insertion of a prosthetic heart valve, resulting in prosthetic-valve endocarditis (PVE).[6]

EPIDEMIOLOGY AND ETIOLOGY

Infective endocarditis is an uncommon, but not rare, infection. Population-based studies have reported incidence rates of 2 to 15 cases per 100,000 person-years.[2,7,8] In the United States, the infection is listed as the primary or secondary diagnosis of 30,000 hospital discharges.[9] Yet, the incidence of infective endocarditis may be increasing, and it is now the fourth leading cause of infectious disease syndromes that are life threatening, after urosepsis, pneumonia, and intraabdominal sepsis.[10] The mean male-to-female ratio is 1.7:1. As the population ages and as valve replacement surgery becomes more common, the mean age of patients with infective endocarditis increases. Overall, most cases occur in individuals older than 50 years of age, and it is uncommon in children.[11,12] PVE accounts for 20% to 25 % of cases of infective endocarditis.[3,12] Those with a history of intravenous drug abuse (IVDA) are also at high risk. Of note, the incidence of healthcare-associated infective endocarditis is rising, especially in the elderly population.[11,12] Other conditions associated with a higher incidence of infective endocarditis include diabetes, long-term hemodialysis, and poor dental hygeine.[2,5]

1 Most persons with infective endocarditis have risk factors, such as preexisting cardiac valvular abnormalities. Many types of structural heart disease result in turbulent blood flow that increases the risk for infective endocarditis. A predisposing risk factor,

however, may be absent in up to 25% of cases. Some of the more important risk factors include:[2,5,12,13]

- Presence of a prosthetic valve (highest risk)
- Previous endocarditis (highest risk)
- Congenital heart disease
- Chronic intravenous access
- Diabetes mellitus
- Healthcare-related exposure
- Acquired valvular dysfunction (e.g., rheumatic heart disease)
- Hypertrophic cardiomyopathy
- Mitral valve prolapse with regurgitation
- IVDA

In the past, rheumatic heart disease was a prevalent risk factor for infective endocarditis, but the incidence of this disease continues to decline. The risk of infective endocarditis in persons with mitral valve prolapse and regurgitation is small; however, because the condition is prevalent, it is an important contributor to the overall number of infective endocarditis cases.[2,5] Prosthetic valve endocarditis occurs in 1% to 3% of patients undergoing valve replacement surgery in the first postoperative year.[3,14]

2 Nearly every organism causing human disease has been reported to cause infective endocarditis, but three groups of organisms result in a majority of cases: streptococci, staphylococci, and enterococci (Table 120–1).[1,3,4,14] The incidence of staphylococci, particularly *S. aureus*, continues to increase, and recent case series document staphylococci have surpassed viridans streptococci as the leading cause of infective endocarditis.[12,13] In general, streptococci cause infective endocarditis in patients with underlying cardiac abnormalities, such as mitral valve prolapse or rheumatic heart disease. Staphylococci (*S. aureus* and coagulase-negative staphylococci) are the most common cause of PVE within the first year after valve surgery, and *S. aureus* is common in those with a history of IVDA. Although polymicrobial infective endocarditis is uncommon, it is encountered most often in association with IVDA.[2,3,5] Enterococcal endocarditis tends to follow genitourinary manipulations (older men) or obstetric procedures (younger women).[3] There are many exceptions to the preceding generalizations; thus, isolation of the causative pathogen and determination of its antimicrobial susceptibilities offer the best chance for successful therapy.

The mitral and aortic valves are affected most commonly in cases involving a single valve. Subacute endocarditis tends to involve the mitral valve, whereas acute disease often involves the aortic valve. Up to 35% of cases involve concomitant infections of both the aortic and the mitral valves. Infection of the tricuspid valve is less common, with a majority of these cases occurring for patients with a history of IVDA. It is rare for the pulmonary valve to be infected.[1,3,12,13]

TABLE 120-1 Etiologic Organisms in Infective Endocarditis

Agent	Percentage of Cases (%)
Streptococci	25–35
Viridans streptococci	10–20
Other streptococci	5–10
Staphylococci	45–70
Coagulase positive	30–60
Coagulase negative	3–25
Enterococci	5–18
Gram-negative aerobic bacilli	1.5–13
Fungi	1–4
Miscellaneous bacteria	<5
Mixed infections	1–2
"Culture negative"	<5–24

Adapted from references 2 and 12.

PATHOPHYSIOLOGY

The development of infective endocarditis via hematogenous spread, the most common route, requires the sequential occurrence of several factors. These components are complex and not fully elucidated.[2,3,15]

- *The endothelial surface of the heart is damaged*. This injury occurs with turbulent blood flow associated with the valvular lesions previously described.
- *Platelet and fibrin deposition occurs on the abnormal epithelial surface*. These platelet-fibrin deposits are referred to as *nonbacterial thrombotic endocarditis*.
- *Bacteremia gives organisms access to and results in colonization of the endocardial surface*. Bacteremia is the result of trauma to a mucosal surface with a high concentration of resident bacteria, such as the oral cavity and gastrointestinal tract. Transient bacteremia commonly follow certain dental, gastrointestinal, urologic, and gynecologic procedures. Staphylococci, viridans streptococci, and enterococci are most likely to adhere to nonbacterial thrombotic endocarditis, probably because of production of specific adherence factors, such as dextran by some oral streptococci and glycocalyx for staphylococci. Gram-negative bacteria rarely adhere to heart valves and are uncommon causes of infective endocarditis.
- *After colonization of the endothelial surface, a "vegetation" of fibrin, platelets, and bacteria forms*. The protective cover of fibrin and platelets allows unimpeded bacterial growth to concentrations as high as 10^9 to 10^{10} organisms per gram of tissue.

The pathogenesis of early PVE differs from the infective endocarditis acquired by the hematogenous route because surgery may directly inoculate the valve with bacteria from the patient's skin or operating room personnel. A recently placed nonendothelialized valve is more susceptible to bacterial colonization than are native valves. Bacteria also may colonize the new valve from contaminated bypass pumps, cannulas, and pacemakers or from a nosocomial bacteremia subsequent to an intravascular catheter.[1,13] The mechanism of bacterial colonization and pathogenesis in late PVE is similar to native-valve endocarditis.[1]

The vegetations seen in infective endocarditis may be single or multiple and vary in size from a few millimeters to centimeters. Bacteria within the vegetation grow slowly and are protected from antibiotics and host defenses. The adverse effects of infective endocarditis and the resulting lesions can be far-reaching and include (a) local perivalvular damage, (b) embolization of septic fragments with potential hematogenous seeding of remote sites, and (c) formation of antibody complexes.[1–3]

Formation of vegetations may destroy valvular tissue, and continued destruction can lead to acute heart failure via perforation of the valve leaflet, rupture of the chordae tendineae or papillary muscle, or for patients with PVE, valve dehiscence. Occasionally, valvular stenosis may occur. Abscesses can develop in the valve ring or in myocardial tissue itself. Even with resolution of the process, fibrosis of tissue with some residual dysfunction is possible.

Vegetations may be friable, and fragments may be released downstream. These infected particles, termed *septic emboli*, can result in organ abscess or infarction. Septic emboli from right-sided endocarditis commonly lodge in the lungs, causing pulmonary

abscesses. Emboli from left-sided vegetations commonly affect organs with high blood flow, such as the kidneys, spleen, and brain.[1–3]

Circulating immune complexes consisting of antigen, antibody, and complement may deposit in organs, producing local inflammation and damage (e.g., glomerulonephritis in the kidneys). Other potential pathologic changes that result from immune-complex deposition or septic emboli include the development of "mycotic" aneurysms (although the aneurysm is usually bacterial in origin, not fungal), cerebral infarction, splenic infarction and abscess, and skin manifestations such as petechiae, Osler nodes, and Janeway lesions.[1,3]

CLINICAL PRESENTATION

3 The clinical presentation of infective endocarditis is highly variable and nonspecific. Fever is the most common finding and is often accompanied by other vague symptoms (Table 120–2). Fever may be relatively low grade, particularly in subacute cases. Heart murmurs are found in a majority of patients, most often preexisting, with some documented as new or changing. Infective endocarditis usually begins insidiously and worsens gradually. Patients may present with nonspecific findings, such as fever, chills, weakness, dyspnea, night sweats, weight loss, or malaise. In contrast, patients with acute disease, such as those with a history of IVDA and *S. aureus* infective endocarditis, may appear with classic signs of sepsis.

Splenomegaly is a frequent finding for patients with prolonged endocarditis. Other important clinical signs especially prevalent in subacute illness may include the following peripheral manifestations ("stigmata") of endocarditis[5,11–13]:

- Osler nodes: Purplish or erythematous subcutaneous papules or nodules on the pads of the fingers and toes. These lesions are 2 to 15 mm in size and are painful and tender. These nodes are not specific for infective endocarditis and may be the result of embolism, immunologic phenomena, or both.
- Janeway lesions: Hemorrhagic, painless plaques on the palms of the hands or soles of the feet. These lesions are believed to be embolic in origin.
- Splinter hemorrhages: Thin, linear hemorrhages found under the nail beds of the fingers or toes. These lesions are not specific for infective endocarditis and more commonly are the result of traumatic injuries. Distal lesions are more likely the result of trauma, whereas proximal lesions tend to be associated with infective endocarditis.
- Petechiae: Small (usually 1 to 2 mm in diameter), erythematous, painless, hemorrhagic lesions. These lesions appear anywhere on the skin but more frequently on the anterior trunk, buccal mucosa and palate, and conjunctivae. Petechiae are nonblanching and resolve after a few days.
- Clubbing of the fingers: Proliferative changes in the soft tissues about the terminal phalanges observed in long-standing endocarditis.
- Roth spots: Retinal infarct with central pallor and surrounding hemorrhage.
- Emboli: Embolic phenomena occur in up to one-third of cases and may result in significant complications. Left-sided endocarditis can result in renal artery emboli causing flank pain with hematuria, splenic artery emboli causing abdominal pain, and cerebral emboli, which may result in hemiplegia or alteration in mental status. Right-sided endocarditis may result in pulmonary emboli, causing pleuritic pain with hemoptysis.

TABLE 120-2 Clinical Presentation of Infective Endocarditis

General
The clinical presentation of infective endocarditis is highly variable and nonspecific.
Symptoms
The patient may complain of fever, chills, weakness, dyspnea, night sweats, weight loss, and/or malaise.
Signs
Fever is common, as is a heart murmur (sometimes new or changing). The patient may have embolic phenomenon, splenomegaly, or skin manifestations (e.g., Osler nodes, Janeway lesions).
Laboratory tests
The patient's white blood cell count may be normal or only slightly elevated. Nonspecific findings include anemia (normocytic, normochromic), thrombocytopenia, an elevated erythrocyte sedimentation rate or C-reactive protein, and altered urinary analysis (proteinuria/microscopic hematuria). The hallmark laboratory finding is continuous bacteremia; three sets of blood cultures should be collected over 24 hours.
Other diagnostic tests
An electrocardiogram, chest radiograph, and echocardiogram are commonly performed. Echocardiography to determine the presence of valvular vegetations plays a key role in the diagnosis of infective endocarditis; it should be performed in all suspected cases.

Patients with infective endocarditis typically have laboratory abnormalities; however, none of these changes is specific for the disease. Anemia (normocytic, normochromic), leukocytosis, and thrombocytopenia may be present. The white blood cell count is often normal or only slightly elevated, sometimes with a mild left shift. Acute bacterial endocarditis, however, may present with an elevated white blood cell count, consistent with a fulminant infection. The erythrocyte sedimentation rate and C-reactive protein may be elevated in approximately 60% of patients. Often the urinary analysis is abnormal, with proteinuria and microscopic hematuria occurring in approximately 25% of individuals.[5,12]

The hallmark of infective endocarditis is a continuous bacteremia caused by bacteria shedding from the vegetation into the bloodstream; 90% to 95% of patients with infective endocarditis have positive blood cultures.[2,3,12] Three sets of blood cultures, each from separate venipuncture sites, should be collected over 24 hours, and antibiotics should be withheld until adequate blood cultures are obtained. On the other hand, if a patient has a toxic appearance, several blood cultures should be collected promptly, followed by immediate empirical antimicrobial treatment. The blood cultures for patients who have received previous antibiotics should be monitored more closely because pathogen growth may be suppressed.[2,14] "Culture negative" endocarditis describes a patient in whom a clinical diagnosis of infective endocarditis is likely but blood cultures do not yield a pathogen. This condition is often the consequence of previous antibiotic therapy, improperly collected blood cultures, or unusual organisms.[4] When blood cultures from patients suspected of having infective endocarditis show no growth after 48 to 72 hours, the laboratory should be advised and cultures held for up to a month to detect growth of fastidious organisms.[2–4,14]

An electrocardiogram, chest radiograph, and echocardiogram are performed for patients suspected of endocarditis. The electrocardiogram rarely shows important diagnostic findings but may reveal heart block, suggesting extension of the infection. The chest radiograph may provide more diagnostic information, especially in a patient with right-sided endocarditis. Septic pulmonary emboli may occur, leading to multiple lung foci. The echocardiogram is the most important test and should be performed for all patients suspected of this infection.

Echocardiography plays an important role in the diagnosis and management of infective endocarditis.[4] The chosen approach, transthoracic echocardiography (TTE) or transesophageal echocardiography (TEE), depends on the clinical setting. The TEE technique is more sensitive for detecting vegetations (90% to 100%) as compared with TTE (58% to 63%), and TEE maintains good specificity (85% to 95%).[3,4] TTE appears reasonable in the evaluation of children or adults in whom the clinical suspicion of infective endocarditis is relatively low.[4,16] TEE is preferred in high-risk patients such as those with prosthetic heart valves, many congenital heart diseases, previous endocarditis, new murmur, heart failure, or other stigmata of endocarditis.[4,17] The lack of vegetation on echocardiogram does not exclude infection even if the transesophageal approach is used. Conversely, the test may reveal an unsuspected large vegetation, extension of the disease into surrounding tissue, valvular defects, abscess formation, cordial rupture, or an intracardiac fistula. Thus, in addition to helping in the diagnosis of infective endocarditis, the echocardiogram allows the physician to evaluate hemodynamic stability and the need for urgent surgical intervention; it also provides a rough estimate of the likelihood of embolism.[4,18]

DIAGNOSIS

4 The signs and symptoms of infective endocarditis are not specific, and the diagnosis is often unclear. The identification of infective endocarditis requires the integration of clinical, laboratory, and echocardiographic findings. The Duke diagnostic criteria include major and minor variables (Table 120–3).[19,20] Based on the number of major and minor criteria that are fulfilled, patients suspected of infective endocarditis are categorized into three separate groups: definite infective endocarditis, possible infective endocarditis, or infective endocarditis rejected.[20]

PROGNOSIS

The outcome for endocarditis is improved with rapid diagnosis, appropriate treatment (i.e., antimicrobial therapy, surgery, or both), and prompt recognition of complications should they arise. Factors associated with increased mortality include (a) heart failure, (b) increasing age, (c) endocarditis caused by resistant organisms such as fungi or gram-negative bacteria, (d) left-sided endocarditis caused by *S. aureus*, (e) paravalvular complications, (f) healthcare-acquired infection, and (g) PVE.[4,5,12,13] The presence of heart failure has the greatest negative impact on the short-term prognosis.[4] For native-valve infective endocarditis, mortality rates range from 20% to 25%; lower rates occur with viridans streptococci (4% to 16%), and higher rates occur with left-sided infective endocarditis caused by enterococci (15% to 25%) and staphylococci (25% to 47%). Even higher rates of mortality are seen with unusually encountered organisms (e.g., mortality greater than 50% for *Pseudomonas aeruginosa*).[4] The mortality rate for right-side infective endocarditis associated with IVDA is generally low (e.g., 10%).[4,5] For those who relapse after treatment for infective endocarditis, most will do so within the first 2 months after discontinuation of antimicrobials. Relapse rates for viridans streptococcus are generally low (2%), whereas relapse is more likely in those with enterococcal infection (8% to 20%) and PVE (10% to 15%).[1,5] After appropriate treatment and recovery, the risk of morbidity and mortality following infective endocarditis persist for years, although it gradually declines annually. Morbidity remains elevated because of a greater likelihood of recurrent infective endocarditis, heart failure, and embolism or, if a valve is replaced, the risk of anticoagulation, valve thrombosis, or additional valve surgery.[21]

TABLE 120-3 Diagnosis of Infective Endocarditis According to the Modified Duke Criteria

Major Criteria
Blood culture positive for infective endocarditis
Typical microorganisms consistent with infective endocarditis from two separate blood cultures:
Viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*; or
Community-acquired enterococci, in the absence of a primary focus; or
Microorganisms consistent with infective endocarditis from persistently positive blood cultures, defined as follows:
At least two positive cultures of blood samples drawn greater than 12 hours apart; or
All of three or a majority of four or more separate cultures of blood (with first and last sample drawn at least 1 hour apart)
Single positive blood culture for *Coxiella burnetii* or antiphase I immunoglobulin G antibody titer >1:800.
Evidence of endocardial involvement
Echocardiogram positive for infective endocarditis (transesophageal echocardiography recommended for patients with prosthetic valves, rated at least "possible infective endocarditis" by clinical criteria, or complicated infective endocarditis [paravalvular abscess]; transthoracic echocardiography as first test for other patients), defined as follows:
Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets or on implanted material in the absence of an alternative anatomic explanation; or
Abscess; or
New partial dehiscence of prosthetic valve
New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)
Minor Criteria
Predisposition, predisposing heart condition, or injection drug use
Fever, temperature >38°C (100.4°F)
Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions
Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor
Microbiologic evidence: Positive blood culture but does not meet a major criterion as noted above or serologic evidence of active infection with organism consistent with infective endocarditis
Echocardiographic minor criteria eliminated

HACEK, *Haemophilus* species (*H. parainfluenzae, H. aphrophilus, H. paraphrophilus*), *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*.
Note: Cases are defined clinically as *definite* if they fulfill two major criteria, one major criterion plus three minor criteria, or five minor criteria; cases are defined as *possible* if they fulfill one major and one minor criterion or three minor criteria. Cases are rejected if there is a firm alternate diagnosis explaining evidence of infective endocarditis; resolution of infective endocarditis syndrome with antibiotic therapy for <4 days; no pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for <4 days; or does not meet criteria for possible infective endocarditis, as above.
Adapted from references 19 and 20.

TREATMENT

Infective Endocarditis

DESIRED OUTCOMES

The desired outcomes for treatment and prophylaxis of infective endocarditis are to:

- Relieve the signs and symptoms of the disease.
- Decrease morbidity and mortality associated with the infection.
- Eradicate the causative organism with minimal drug exposure.
- Provide cost-effective antimicrobial therapy determined by the likely or identified pathogen, drug susceptibilities,

hepatic and renal function, drug allergies, and anticipated drug toxicities.

- Prevent infective endocarditis from occurring or recurring in high-risk patients with appropriate prophylactic antimicrobials.

GENERAL APPROACH TO TREATMENT

5 The most important approach in the treatment of infective endocarditis is isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by high-dose, parenteral, bactericidal antibiotics for an extended period.[1,2,5] Identification of susceptibilities is crucial given the escalating level of antibiotic resistance to commonly encountered pathogens. Treatment usually is started in the hospital, but for select patients it is often completed in the outpatient setting so long as defervescence has occurred and followup blood cultures show no growth.[5,22] Large doses of parenteral antimicrobials usually are necessary to achieve bactericidal concentrations within vegetations. An extended duration of therapy is required, even for susceptible pathogens, because microorganisms are enclosed within valvular vegetations and fibrin deposits. These barriers impair host defenses and protect microbes from phagocytic cells. In addition, high bacterial concentrations within vegetations may result in an inoculum effect that further resists killing (see Chap. 113 for additional discussion). Many bacteria are not actively dividing, further limiting the rate of bacterial death. For most patients, 4 to 6 weeks of therapy is required.[2,3]

NONPHARMACOLOGIC THERAPY

6 Surgery is an important adjunct in the management of endocarditis. In most surgical cases, valvectomy and valve replacement are performed to remove infected tissue and to restore hemodynamic function. Echocardiographic features that suggest the need for surgery include persistent vegetation or an increase in vegetation size after prolonged antibiotic treatment, valve dysfunction, or paravalvular extension (e.g., abscess).[4,23] Surgery also may be considered in cases of PVE endocarditis caused by resistant organisms (e.g., fungi or gram-negative bacteria), or if there is persistent bacteremia or other evidence of failure despite appropriate antimicrobial therapy.[1,3,23,24] Surgical intervention is also appropriate if heart failure is present in left-sided infective endocarditis and when there is persistent infection in right-sided infective endocarditis.[1,5,23]

PHARMACOLOGIC THERAPY

Specific treatment recommendations from the American Heart Association (AHA) provide guidance for the management of infective endocarditis and these were updated in 2005.[4] Guidelines, published in 2009 by the European Society of Cardiology, are consistent with the AHA.[25] Both guidelines use an evidence-based scoring system where recommendations are given a classification as well as level of evidence. Class I recommendations are conditions for which there is evidence, general agreement, or both that a given procedure or treatment is useful and effective. Class II recommendations are conditions for which there is conflicting evidence, a divergence of opinion, or both about the usefulness/efficacy of a procedure or treatment (IIa implies the weight of evidence/opinion is in favor of usefulness/efficacy whereas IIb implies usefulness/efficacy is less well established by evidence/opinion). Class III recommendations are conditions for which there is evidence, general agreement, or both that the procedure/treatment is not useful/effective and in some cases may be harmful. Level of evidence is listed as A (data derived from multiple randomized clinical trials), B (data derived from a single randomized trial or nonrandomized studies), and C (consensus opinion of experts).

7 β-Lactam antibiotics, such as penicillin G (or ceftriaxone), nafcillin, and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal endocarditis, respectively. Tables 120–4 through 120–11 summarize these recommendations, which are discussed in more detail in the following sections. Because these guidelines focus on common causes of endocarditis, readers are referred to other references for more in-depth discussion of unusually encountered organisms.[4,10,26]

8 For some pathogens, such as enterococci, the use of synergistic antimicrobial combinations (including an aminoglycoside) is essential to obtain a bactericidal effect. Combination antibiotics also may decrease the emergence of resistant organisms during treatment (e.g., PVE caused by coagulase-negative staphylococci) and hasten the pace of clinical and microbiologic response (e.g., some streptococcal and staphylococcal infections). Occasionally, combination treatment will result in a shorter treatment course.

STREPTOCOCCAL ENDOCARDITIS

Streptococci are a common cause of infective endocarditis, with most isolates being viridans streptococci. *Viridans streptococci* refer to a large number of different species, such as *Streptococcus sanguinis, Streptococcus oralis, Streptococcus salivarius, Streptococcus mutans*, and *Gemella morbillorum*.[4] These bacteria are common inhabitants of the human mouth and gingiva, and they are especially common causes of endocarditis involving native valves.[4,13,27] During dental surgery, and even when brushing the teeth, these organisms can cause a transient bacteremia. In susceptible individuals, this may result in infective endocarditis. Streptococcal endocarditis is usually subacute, and the response to medical treatment is very good. *Streptococcus bovis* is not a viridans streptococcus, but it is included in this treatment group because it is penicillin sensitive and requires the same treatment as viridans streptococci. *S. bovis* is a nonenterococcal group D *Streptococcus* that resides in the gastrointestinal tract. Infective endocarditis caused by this organism is often associated with a gastrointestinal pathology, especially colon carcinoma. Endocarditis caused by *Streptococcus pneumoniae, Streptococcus pyogenes*, and groups B, C, and G streptococci are uncommon, and their treatment is not well defined.[4,27]

Antimicrobial regimens for viridans streptococci are well studied, and in uncomplicated cases, response rates as high as 98% can be expected. Viridans streptococci are penicillin susceptible, although some are more susceptible than others. Most are exquisitely sensitive to penicillin G and have minimal inhibitory concentrations (MICs) of less than 0.12 mcg/mL.[4,27] Approximately 10% to 20% are moderately susceptible (MIC 0.12 to 0.5 mcg/mL). This difference in in vitro susceptibility led to recommendations that the MIC be determined for all viridans streptococci and that the results be used to guide therapy. Some streptococci are deemed tolerant to the killing effects of penicillin, where the minimal bactericidal concentration (MBC) exceeds the MIC by 32 times. A tolerant organism is inhibited but not killed by an antibiotic normally considered bactericidal.[4] Bactericidal activity is required for successful treatment of infective endocarditis; therefore, infections with a tolerant organism may relapse after treatment. Despite some animal studies of endocarditis suggesting that tolerant strains do not respond as readily to β-lactam therapy as nontolerant ones, this phenomenon is primarily a laboratory finding with little clinical significance.[3,4] Treatment for tolerant strains is identical to that for nontolerant organisms, and measurement of the MBC is not recommended.[4]

An assortment of regimens can be used to treat uncomplicated, native-valve endocarditis caused by fully susceptible viridans streptococci (Table 120–4). Two single-drug regimens consist of high-dose parenteral penicillin G or ceftriaxone for 4 weeks. If a shorter course of therapy is desired, the guidelines suggest high-dose

TABLE 120-4 Therapy of Native Valve Endocarditis Caused by Highly Penicillin-Susceptible Viridans Group Streptococci and *Streptococcus bovis*

Regimen	Dosage[a] and Route	Duration (week)	Strength of Recommendation	Comments
Aqueous crystalline penicillin G sodium	12–18 million units/24 hours IV either continuously or in four or six equally divided doses	4	I A	Preferred for most patients older than age 65 years or patients with impairment of 8th cranial nerve function or renal function
or				
Ceftriaxone sodium	2 g/24 hours IV/IM in one dose Pediatric dose[b]: penicillin 200,000 units/kg per 24-hour IV in four to six equally divided doses; ceftriaxone 100 mg/kg per 24 hours IV/IM in 1 dose	4	I A	
Aqueous crystalline penicillin G sodium	12–18 million units/24 hours IV either continuously or in six equally divided doses	2	I B	2-week regimen not intended for patients with known cardiac or extracardiac abscess or for those with creatinine clearance of <20 mL/min, impaired 8th cranial nerve function, or *Abiotrophia, Granulicatella*, or *Gemella* spp. infection; gentamicin dosage should be adjusted to achieve peak serum concentration of 3–4 mcg/ mL and trough serum concentration of <1 mcg/mL when three divided doses are used (second option to single daily dose)
or				
Ceftriaxone sodium	2 g/24 hours IV/IM in 1 dose	2	I B	
plus				
Gentamicin sulfate[c]	3 mg/kg per 24 hours IV/IM in 1 dose Pediatric dose: penicillin 200,000 units/kg per 24 hours IV in four to six equally divided doses; ceftriaxone 100 mg/kg per 24 hours IV/IM in 1 dose; gentamicin 3 mg/kg per 24 hours IV/IM in one dose or three equally divided doses[d]	2		
Vancomycin hydrochloride[e]	30 mg/kg per 24 hours IV in two equally divided doses not to exceed 2 g/24 hours unless concentrations are inappropriately low Pediatric dose: 40 mg/kg per 24 hours IV in two to three equally divided doses	4	I B	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone; vancomycin dosage should be adjusted to obtain peak (1 hour after infusion completed) serum concentration of 30–45 mcg/mL and a trough concentration range of 15–20 mcg/mL

Minimum inhibitory concentration <0.12 mcg/mL.
[a]Dosages recommended are for patients with normal renal function.
[b]Pediatric dose should not exceed that of a normal adult.
[c]Other potentially nephrotoxic drugs (e.g., nonsteroidal antiinflammatory drugs) should be used with caution for patients receiving gentamicin therapy.
[d]Data for once-daily dosing of aminoglycosides for children exist, but no data for treatment of infective endocarditis exist.
[e]Vancomycin dosages should be infused during course of at least 1 hour to reduce risk of histamine-release "red man" syndrome.

TABLE 120-5 Therapy of Native Valve Endocarditis Caused by Strains of Viridans Group Streptococci and *Streptococcus bovis* Relatively Resistant to Penicillin

Regimen	Dosage[a] and Route	Duration (week)	Strength of Recommendation	Comments
Aqueous crystalline penicillin G sodium	24 million units/24 hours IV either continuously or in four to six equally divided doses	4	I B	Patients with endocarditis caused by penicillin-resistant (MIC >0.5 mcg/mL) strains should be treated with regimen recommended for enterococcal endocarditis (see Table 120–9)
or				
Ceftriaxone sodium	2 g/24 hours IV/IM in one dose	4	I B	
plus				
Gentamicin sulfate[b]	3 mg/kg per 24 hours IM/IV in one dose Pediatric dose[c]: penicillin 300,000 units/24 hours IV in four to six equally divided doses; ceftriaxone 100 mg/kg per 24 hours IV/IM in one dose; gentamicin 3 mg/kg per 24 hours IV/IM in one dose or three equally divided doses	2		Although it is preferred that gentamicin (3 mg/kg) be given as a single daily dose to adult patients, as a second option, gentamicin can be administered daily in three equally divided doses
Vancomycin hydrochloride[c]	30 mg/kg per 24 hours IV in two equally divided doses not to exceed 2 g/24 hours unless serum concentrations are inappropriately low Pediatric dose: 40 mg/kg per 24 hours in two or three equally divided doses	4	I B	Vancomycin[d] therapy recommended only for patients unable to tolerate penicillin or ceftriaxone therapy

Minimum inhibitory concentration (MIC) >0.12 mcg/mL to ≥0.5 mcg/mL.
[a]Dosages recommended are for patients with normal renal function.
[b]See Table 120–4 for appropriate dosage of gentamicin.
[c]Pediatric dose should not exceed that of a normal adult.
[d]See Table 120–4 for appropriate dosage of vancomycin.

TABLE 120-6 Therapy for Endocarditis of Prosthetic Valves or Other Prosthetic Material Caused by Viridans Group Streptococci and *Streptococcus bovis*

Regimen	Dosage[a] and Route	Duration (week)	Strength of Recommendation	Comments
Penicillin-susceptible strain (minimum inhibitory concentration ≤0.12 mcg/mL)				
Aqueous crystalline penicillin G sodium	24 million units/24 hours IV either continuously or in four to six equally divided doses	6	I B	Penicillin or ceftriaxone together with gentamicin has not demonstrated superior cure rates compared with monotherapy with penicillin or ceftriaxone for patients with highly susceptible strain; gentamicin therapy should not be administered to patients with creatinine clearance of <30 mL/min
or				
Ceftriaxone sodium	2 g/24 hours IV/IM in one dose	6	I B	
with or without				
Gentamicin sulfate[b]	3 mg/kg per 24 hours IM/IV in one dose Pediatric dose[c]: penicillin 300,000 units/24 hours IV in four to six equally divided doses; ceftriaxone 100 mg/kg per 24 hours IV/IM in one dose; gentamicin 3 mg/kg per 24 hours IV/IM in one dose or three equally divided doses	2		
Vancomycin hydrochloride[d]	30 mg/kg per 24 hours IV in two equally divided doses Pediatric dose: 40 mg/kg per 24 hours in two or three equally divided doses	2	I B	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone therapy
Penicillin relatively or fully resistant strain (minimum inhibitory concentration >0.12 mcg/mL)				
Aqueous crystalline penicillin sodium	24 million units per 24 hours IV either continuously or in four to six equally divided doses	6	I B	
or				
Ceftriaxone	2 g/24 hours IV/IM in one dose	6	I B	
plus				
Gentamicin sulfate	3 mg/kg per 24 hours IV/IM in one dose Pediatric dose: penicillin 300,000 units/kg per 24 hours IV in four to six equally divided doses	6		
Vancomycin hydrochloride	30 mg/kg per 24 hours IV in two equally divided doses Pediatric dose: 40 mg/kg per 24 hours IV in two or three equally divided doses	6	I B	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone therapy

[a]Dosages recommended are for patients with normal renal function.
[b]See Table 120–4 for appropriate dosage of gentamicin.
[c]Pediatric dose should not exceed that of a normal adult.
[d]See text and Table 120–4 for appropriate dosage of vancomycin.

parenteral penicillin G plus an aminoglycoside.[4] When used in select patients, this combination is as effective as 4 weeks of penicillin alone. Although streptomycin was listed in previous guidelines, gentamicin is the preferred aminoglycoside because serum drug concentrations are obtained easily, clinicians are more familiar with its use, and the few strains of streptococci resistant to the effects of streptomycin-penicillin remain susceptible to gentamicin-penicillin. Other aminoglycosides are not recommended.

The decision of which regimen to use depends on the perceived risk versus benefit. For example, a 2-week course of gentamicin in an elderly patient with renal impairment may be associated with ototoxicity, worsening renal function, or both. Furthermore, the 2-week regimen is not recommended for patients with known extracardiac infection. On the other hand, a 4-week course of penicillin alone generally entails greater expense, especially if the patient remains in the hospital. Monotherapy with once-daily ceftriaxone offers ease of administration, facilitates home healthcare treatment, and may be cost-effective.[4,28]

The British Society for Antimicrobial Chemotherapy guidelines suggest that all of the following conditions be present to consider a 2-week treatment regimen for penicillin-sensitive streptococcal endocarditis:[26,29]

- Penicillin-sensitive viridans streptococcus or *S. bovis* (penicillin MIC <0.1 mcg/mL)
- No cardiovascular risk factors such as heart failure, aortic insufficiency, or conduction abnormalities
- No evidence of thromboembolic disease
- Native-valve infection
- No vegetation of greater than 5 mm diameter on echocardiogram
- Clinical response within 7 days (the temperature should return to normal, the patient should feel well, and the patient's appetite should return to normal)

9 When a patient has a history of an immediate-type hypersensitivity to penicillin, vancomycin should be chosen for infective endocarditis caused by viridans streptococci. When vancomycin is used, the addition of gentamicin is not recommended.[4] Most patients who report a penicillin allergy have a negative penicillin skin test and consequently are at low risk of anaphylaxis.[30] The published experience with penicillin is more extensive than with alternative regimens; consequently, a thorough allergy history must be obtained before a second-line therapy is administered.

For patients with complicated infections (e.g., extracardiac foci) or when the streptococcus has an MIC of 0.12 to less than or equal to 0.5 mcg/mL, combination therapy with an aminoglycoside for the first 2 weeks and penicillin (higher dose) or ceftriaxone is recommended, followed by penicillin or ceftriaxone alone for an additional 2 weeks (**Table 120–5**).[4] Some viridans streptococci have biologic characteristics that complicate diagnosis and treatment, previously referred to as nutritionally variant streptococci. *Abiotrophia defectiva* and *Granulicatella* species have nutritional deficiencies that hinder growth in routine culture media.[3,4,27] These organisms require special broth supplemented with pyridoxal hydrochloride or cysteine. For patients infected with nutritionally

TABLE 120-7 Therapy for Endocarditis Caused by Staphylococci in the Absence of Prosthetic Materials

Regimen	Dosage[a] and Route	Duration	Strength of Recommendation	Comments
Oxacillin-susceptible strains				
Nafcillin or oxacillin[b] ***with***	12 g/24 hours IV in four to six equally divided doses	6 weeks	I A	For complicated right-sided infective endocarditis and for left-sided infective endocarditis; for uncomplicated right-sided infective endocarditis, 2 weeks (see text)
Optional addition of gentamicin sulfate[c]	3 mg/kg per 24 hours IV/IM in two or three equally divided doses	3–5 days		Clinical benefit of aminoglycosides has not been established
For penicillin-allergic (nonanaphylactoid type) patients:				Consider skin testing for oxacillin-susceptible staphylococci and questionable history of immediate-type hypersensitivity to penicillin
Cefazolin ***with***	6 g/24 hours IV in three equally divided doses	6 weeks	I B	Cephalosporins should be avoided in patients with anaphylactoid-type hypersensitivity to β-lactams; vancomycin should be used in these cases[d]
Optional addition of gentamicin sulfate	3 mg/kg per 24 hours IV/IM in two or three equally divided doses Pediatric dose: cefazolin 100 mg/kg per 24 hours IV in three equally divided doses; gentamicin 3 mg/kg per 24 hours IV/IM in three equally divided doses	3–5 days		Clinical benefit of aminoglycosides has not been established
Oxacillin-resistant strains				
Vancomycin[e]	30 mg/kg per 24 IV in two equally divided doses Pediatric dose: 40 mg/kg per 24 hours IV in two or three equally divided doses	6 weeks	I B	Adjust vancomycin dosage to achieve 1-hour serum concentration of 30–45 mcg/mL and trough concentration of 15–20 mcg/mL

[a]Dosages recommended are for patients with normal renal function.
[b]Penicillin G 24 million units/24 hours IV in four to six equally divided doses may be used in place of nafcillin or oxacillin if strain is penicillin susceptible (minimum inhibitory concentration ≤0.1 mcg/mL) and does not produce β-lactamase.
[c]Gentamicin should be administered in close temporal proximity to vancomycin, nafcillin, or oxacillin dosing. See Table 120–4 for appropriate dosage of gentamicin.
[d]Pediatric dose should not exceed that of a normal adult.
[e]For specific dosing adjustment and issues concerning vancomycin, see Table 120–4 footnotes.
From reference 4, with permission. Copyright 2005, American Medical Association.

variant streptococci or when the *Streptococcus* has an MIC of more than 0.5 mcg/mL, treatment should follow the enterococcal endocarditis treatment guidelines.[4]

The rationale for combination therapy of penicillin-susceptible viridans streptococci is that enhanced activity against these organisms usually is observed when cell-wall active agents are combined with aminoglycosides in vitro.[31] Combined treatment results in quicker sterilization of vegetations in animal models of endocarditis and probably explains the high response rates observed for patients treated for a total of 2 weeks.[4,32] The combined treatment, however, is not superior to penicillin alone. Some authors question the need for combination therapy in relatively resistant streptococci, emphasizing that few human data suggest that patients with endocarditis caused by these organisms respond less well to penicillin alone.[31,33]

For patients with endocarditis of prosthetic valves or other prosthetic material caused by viridans streptococci and *S. bovis*, choices of treatment are similar to those without prosthetic material (e.g., penicillin or ceftriaxone); however, treatment courses are extended to 6 weeks (**Table 120–6**). In fact, if the organism is relatively resistant, gentamicin is recommended for 6 weeks.

Whether extended-interval aminoglycoside dosing has a role in infective endocarditis continues to be debated. At this time, data support extended-interval dosing for the treatment of streptococcal infective endocarditis, and as compared with three-times-daily dosing this approach may have greater efficacy.[34–37] One study specifically evaluated the combination of ceftriaxone (2 g daily) with gentamicin (3 mg/kg daily) for 2 weeks compared with ceftriaxone (2 g daily) alone for 4 weeks for penicillin-sensitive streptococci. Both regimens were safe and effective with similar clinical cure rates at 3 months following treatment.[32]

CLINICAL CONTROVERSY

In the past, the AHA guidelines recommended traditional aminoglycoside dosing (three times daily) whenever clinicians use these antibiotics. Extended-interval dosing (once-daily administration) is an intriguing dosing strategy, but data only support this approach for the treatment of streptococcal infective endocarditis.

STAPHYLOCOCCAL ENDOCARDITIS

Endocarditis caused by staphylococci has become more prevalent, mainly because of increased IVDA, more frequent use of peripheral and central venous catheters, and increased frequency of valve-replacement surgery.[38,39] *S. aureus* is the most common organism causing infective endocarditis among those with IVDA and persons with venous catheters. Coagulase-negative staphylococci (usually *Staphylococcus epidermidis*) are prominent causes of PVE.

Staphylococcal endocarditis is not a homogeneous disease; appropriate management requires consideration of several questions: Is the organism methicillin resistant? Should combination therapy be used? Is the infection on a native or prosthetic valve? Does the patient have a history of IVDA? Is the infection on the left or right side of the heart? Another consideration in staphylococcal endocarditis is that some organisms may exhibit tolerance to antibiotics. Similar to streptococci, however, the concern for tolerance among staphylococci should not affect antibiotic selection.[4]

TABLE 120-8 Therapy for Prosthetic Valve Endocarditis Caused by Staphylococci

Regimen	Dosage[a] and Route	Duration (week)	Strength of Recommendation	Comments
Oxacillin-susceptible strains				
Nafcillin or oxacillin ***plus***	12 g/24 hours IV in four to six equally divided doses	≥6	I B	Penicillin G 24 million units per 24 hours IV in four to six equally divided doses may be used in place of nafcillin or oxacillin if strain is penicillin susceptible (minimum inhibitory concentration ≤0.1 mcg/ mL) and does not produce β-lactamase; vancomycin should be used in patients with immediate-type hypersensitivity reactions to β-lactam antibiotics (see Table 120–4 for dosing guidelines); cefazolin may be substituted for nafcillin or oxacillin for patients with nonimmediate-type hypersensitivity reactions to penicillins
Rifampin ***plus***	900 mg per 24 hours IV/orally in three equally divided doses	≥6		
Gentamicin[b]	3 mg/kg per 24 hours IV/IM in two or three equally divided doses Pediatric dose[c]: nafcillin or oxacillin 200 mg/kg per 24 hours IV in four to six equally divided doses; rifampin 20 mg/kg per 24 hours IV/orally in three equally divided doses; gentamicin 3 mg/kg per 24 hours IV/IM in three equally divided doses	2		
Oxacillin-resistant strains				
Vancomycin ***plus***	30 mg/kg per 24 hours in two equally divided doses	≥6	I B	Adjust vancomycin to achieve 1-hour serum concentration of 30–45 mcg/mL and trough concentration of 15–20 mcg/mL
Rifampin ***plus***	900 mg/24 hours IV/orally in three equally divided doses	≥6		
Gentamicin	3 mg/kg per 24 hours IV/IM in two or three equally divided doses Pediatric dose: vancomycin 40 mg/kg per 24 hours IV in two or three equally divided doses; rifampin 20 mg/kg per 24 hours IV/orally in three equally divided doses (up to adult dose); gentamicin 3 mg/kg per 24 hours IV or IM in three equally divided doses	2		

[a]Dosages recommended are for patients with normal renal function.
[b]Gentamicin should be administered in close proximity to vancomycin, nafcillin, or oxacillin dosing. See Table 120–4 for appropriate dosage of gentamicin.
[c]Pediatric dose should not exceed that of a normal adult.

TABLE 120-10 Therapy for Both Native and Prosthetic Valve Endocarditis Caused by HACEK[a] Microorganisms

Regimen	Dosage and Route	Duration (week)	Strength of Recommendation	Comments
Ceftriaxone[b] sodium	2 g/24 hours IV/IM in one dose	4	I B	Cefotaxime or another third- or fourth-generation cephalosporin may be substituted
or				
Ampicillin-sulbactam[c]	12 g/24 hours IV in four equally divided doses	4	IIa B	
or				
Ciprofloxacin[c,d]	1,000 mg/24 hours orally or 800 mg/24 hours IV in two equally divided doses Pediatric dose[e]: Ceftriaxone 100 mg/kg per 24 hours IV/IM once daily; ampicillin-sulbactam 300 mg/kg per 24 hours IV divided into four or six equally divided doses; ciprofloxacin 20–30 mg/kg per 24 hours IV/orally in two equally divided doses	4	IIb C	Fluoroquinolone therapy recommended only for patients unable to tolerate cephalosporin and ampicillin therapy; levofloxacin, gatifloxacin, or moxifloxacin may be substituted; fluoroquinolones generally not recommended for patients younger than 18 years old Prosthetic valve: Patients with endocarditis involving prosthetic cardiac valve or other prosthetic cardiac material should be treated for 6 weeks.

[a]*Haemophilus parainfluenzae, H. aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella kingae.*
[b]Patients should be informed that IM injection of ceftriaxone is painful.
[c]Dosage recommended for patients with normal renal function.
[d]Fluoroquinolones are highly active in vitro against HACEK microorganisms. Published data on use of fluoroquinolone therapy for endocarditis caused by HACEK are minimal.
[e]Pediatric dose should not exceed that of a normal adult.

Any patient who develops staphylococcal bacteremia is at risk for endocarditis. Many investigators have attempted to develop criteria that identify the bacteremic patient likely to have infective endocarditis.[38,39] In the past, patients were considered to be at high risk for infective endocarditis if *S. aureus* bacteremia was community acquired versus hospital acquired.[19] However, nosocomial *S. aureus* bacteremia is now considered as a major criterion for development of infective endocarditis.[20] In hospitalized patients with *S. aureus* bacteremia and an identified focus of infection, such as a vascular catheter, the risk of concomitant infective endocarditis is low, and treatment of the bacteremia can be reduced to 2 weeks. This approach applies only if the patient does not have a prosthetic valve or additional clinical evidence for endocarditis.[39,40] Additionally, the following parameters predict higher risk of infective endocarditis for patients with *S. aureus* bacteremia: (a) the absence of a primary site of infection, (b) metastatic signs of infection, and (c) valvular vegetations detected by echocardiography.[10,20]

The recommended therapy for patients with left-sided, native-valve infective endocarditis caused by methicillin-sensitive *S. aureus* (MSSA) is 6 weeks of nafcillin or oxacillin, often combined with a short course of gentamicin (Table 120–7). Four weeks of mono-therapy with nafcillin or oxacillin may be sufficient for uncomplicated infections (no perivalvular abscess or septic metastatic complications). From in vitro studies, the combination of an aminoglycoside and penicillinase-resistant penicillin or vancomycin enhances the activity of these drugs for MSSA. In animal models of endocarditis, combinations of penicillin with an aminoglycoside eradicate organisms from vegetations more rapidly than penicillins alone.[31,41] In human studies, the addition of an aminoglycoside to nafcillin hastens the resolution of fever and bacteremia, but it does not affect survival or relapse rates and can increase renal toxicity.[31,42,43] Traditional twice- or three-times-daily dosing of aminoglycosides is recommended when administered for staphylococcal infective endocarditis, however there is a report with gentamicin given once a day.[44]

If a patient has a mild, delayed allergy to penicillin, first-generation cephalosporins (such as cefazolin) are effective alternatives, but they should be avoided for patients with a history of immediate-type hypersensitivity reactions to penicillins (see Table 120–7). The potential for a true immediate-type allergy should be assessed carefully. A penicillin skin test should be conducted before giving antibiotic treatment to any patient with infective endocarditis caused by MSSA if there is a questionable penicillin allergy.[45] 9 For a patient with a positive skin test or a history of immediate hypersensitivity to penicillin, vancomycin is chosen. Vancomycin, however, kills *S. aureus* slowly and is regarded as inferior to penicillinase-resistant penicillins for MSSA.[39] Alternatively, patients with immediate-type hypersensitivity reactions to penicillin who fail to respond to vancomycin therapy should be considered for penicillin desensitization.[4] Generally, antibiotic therapy should be continued for 6 weeks. Unfortunately, left-sided infective endocarditis caused by *S. aureus* continues to have a poor prognosis, with a mortality rate of 25% to 47%.[5] For reasons discussed in the following section, those with infective endocarditis associated with IVDA have a more favorable response to therapy.

During the past decade, staphylococci more commonly are resistant to penicillinase-resistant penicillins (e.g., methicillin). 9 Vancomycin is used in this situation because most methicillin-resistant *S. aureus* (MRSA) and coagulase-negative staphylococci are susceptible to it (see Table 120–7). Reports of *S. aureus* strains resistant to vancomycin are emerging.[46] This is concerning as there are currently no standard treatment regimens to treat *S. aureus* infective endocarditis if the strain is resistant to both methicillin and vancomycin. There is literature documenting success with daptomycin or linezolid for these patients.[46–53] Based on available data, daptomycin (at a dose of 6 mg/kg per day) was approved by the Food and Drug Administration (FDA) in 2006 for the treatment of *S. aureus* bacteremia associated with right-sided infective endocarditis.[46,50,54] To date, linezolid has not been approved by the FDA for use in endocarditis as most available data are based on case reports, and there is concern regarding use of a bacteriostatic agent for this condition.[46,47,54] Furthermore, the FDA issued a warning for linezolid in 2007 following reports from one study that patients with catheter-related bacteremia treated with linezolid had an increased incidence of death due to gram-negative bacillary infections.[55] The presence or lack of a prosthetic heart valve in patients with a methicillin-resistant organism guides therapy and determines whether vancomycin should be used alone or, if a prosthetic valve is present, whether combination therapy is necessary (Table 120–8).[4,56]

TABLE 120-11 Therapy for Culture-Negative Endocarditis Including *Bartonella* Endocarditis

Regimen	Dosage[a] and Route	Duration (week)	Strength of Recommendation	Comments
Native valve				
Ampicillin-sulbactam	12 g/24 hours IV in four equally divided doses	4–6	IIb C	Patients with culture-negative endocarditis should be treated with consultation with an infectious diseases specialist
plus				
Gentamicin sulfate[b]	3 mg/kg per 24 hours IV/IM in three equally divided doses	4–6		
Vancomycin[c]	30 mg/kg per 24 hours IV in 2 equally divided doses	4–6	IIb C	Vancomycin recommended only for patients unable to tolerate penicillins
plus				
Gentamicin sulfate	3 mg/kg per 24 hours IV/IM in three equally divided doses	4–6		
plus				
Ciprofloxacin	1,000 mg/24 hours orally or 800 mg/24 hours IV in two equally divided doses Pediatric dose[d]: ampicillin-sulbactam 300 mg/kg per 24 hours IV in four to six equally divided doses; gentamicin 3 mg/kg per 24 hours IV/IM in three equally divided doses; vancomycin 40 mg/kg per 24 hours in two or three equally divided doses; ciprofloxacin 20–30 mg/kg per 24 hours IV/orally in two equally divided doses	4–6		
Prosthetic valve (early, <1 year)				
Vancomycin	30 mg/kg per 24 hours IV in two equally divided doses	6	IIb C	
plus				
Gentamicin sulfate	3 mg/kg per 24 hours IV/IM in three equally divided doses	2		
plus				
Cefepime	6 g/24 hours IV in three equally divided doses	6		
plus				
Rifampin	900 mg/24 hours orally/IV in three equally divided doses Pediatric dose: vancomycin 40 mg/kg per 24 hours IV in two or three equally divided doses; gentamicin 3 mg/kg per 24 hours IV/IM in three equally divided doses; cefepime 150 mg/kg per 24 hours IV in three equally divided doses; rifampin 20 mg/ kg per 24 hours orally/IV in three equally divided doses	6		
Prosthetic valve (late, >1 year)		6	IIb C	Same regimens as listed above for native valve endocarditis with the addition of rifampin
Suspected *Bartonella*, culture negative				
Ceftriaxone sodium	2 g/24 hours IV/IM in one dose	6	IIa B	Patients with *Bartonella* endocarditis should be treated in consultation with an infectious diseases specialist
plus				
Gentamicin sulfate	3 mg/kg per 24 hours IV/IM in three equally divided doses	2		
with/without				
Doxycycline	200 mg per 24 hours IV/orally in two equally divided doses	6		
Documented *Bartonella*, culture positive				
Doxycycline	200 mg/24 hours IV or orally in two equally divided doses	6	IIa B	If gentamicin cannot be given, then replace with rifampin, 600 mg/24 hours orally/IV in two equally divided doses
plus				
Gentamicin sulfate	3 mg/kg per 24 hours IV/IM in three equally divided doses *Pediatric dose*: ceftriaxone 100 mg/kg per 24 hours IV/IM once daily; gentamicin 3 mg/kg per 24 hours IV/IM in three equally divided doses; doxycycline 2–4 mg/kg per 24 hours IV/orally in two equally divided doses; rifampin 20 mg/kg per 24 hours orally/IV in two equally divided doses	2		

[a]Dosages recommended are for patients with normal renal function.
[b]See text and Table 120–4 for appropriate dosing of gentamicin.
[c]See Table 120–4 for appropriate dosing of vancomycin.
[d]Pediatric dose should not exceed that of a normal adult.

Staphylococcus Endocarditis: Intravenous Drug Abuser

Infective endocarditis in those with IVDA is frequently (60% to 70%) caused by *S. aureus*, although other organisms may be common in certain geographic locations.[57] In this setting, the tricuspid valve is frequently infected, resulting in right-sided infective endocarditis. Most patients have no history of valve abnormalities, are usually otherwise healthy, and have a good response to medical treatment. Nonetheless, surgery may be required.

An uncomplicated, left-sided MSSA endocarditis may be treated sufficiently with 4 weeks of monotherapy with penicillinase-resistant penicillin.[4] For the intravenous drug abuser, however, the clinical response with right-sided MSSA endocarditis is usually excellent. These patients may be treated effectively (clinical and microbiologic cure exceeding 85%) with a 2-week course of nafcillin or oxacillin plus an aminoglycoside.[57–64] Short-course vancomycin, in place of nafcillin or oxacillin, appears ineffective.[59] Another trial suggested that a 2-week regimen of a penicillinase-resistant penicillin alone, without the addition of an aminoglycoside, is as effective as combined therapy in MSSA tricuspid valve endocarditis.[65] Although these data suggest that an aminoglycoside is unnecessary for short-course treatment in the intravenous drug abuser with right-sided infective endocarditis, most clinicians are uncomfortable with monotherapy and choose combination treatment so long as there are no reasons to avoid an aminoglycoside. Short-course therapy should not be used in left-sided endocarditis, and it is inappropriate for patients with underlying acquired immunodeficiency syndrome, renal failure, meningitis, or substantial pulmonary complications, such as lung abscess from right-sided infective endocarditis.[4]

An intriguing therapeutic approach for staphylococcal endocarditis in those with IVDA is oral treatment. Preliminary data suggest that short-course intravenous treatment (primarily nafcillin; mean: 16 days) followed by oral treatment (dicloxacillin or oxacillin; mean: 26 days) might be effective for tricuspid valve MSSA endocarditis.[66] The positive results of this trial can be explained by the duration of intravenous antibiotics (>2 weeks), which may be a sufficient treatment course. Yet, two other studies that predominantly used oral therapy (ciprofloxacin and rifampin) found this approach to be effective (cure rates exceeding 90%) in addicts with uncomplicated right-sided endocarditis caused by MSSA.[67,68] At this time, concerns with resistance (e.g., ciprofloxacin) and limited published data preclude routine use of oral antibacterial regimens for the treatment of infective endocarditis in the intravenous drug abuser.[4]

Staphylococcal Endocarditis: Prosthetic Valves

PVE accounts for approximately 15% of all infective endocarditis cases.[7] An episode of PVE occurring within 2 months of surgery strongly suggests that the cause is staphylococci implanted during the procedure.[1] Yet the risk of staphylococcal endocarditis remains elevated for up to 12 months after valve replacement. Because this type of infective endocarditis is typically a nosocomial infection, methicillin-resistant organisms are common, and vancomycin is the cornerstone of therapy. Combination antimicrobials are recommended because of the high morbidity and mortality associated with PVE and its refractoriness to therapy.[4,12] Although the addition of rifampin to a penicillinase-resistant penicillin or vancomycin does not result in predictable bacterial synergism, rifampin may have unique activity against staphylococcal infection that involves prosthetic material, where its addition results in a higher microbiologic cure rate.[54] Combination therapy also decreases the emergence of resistance to rifampin, which frequently occurs when it is used alone. For methicillin-resistant staphylococci (both MRSA and coagulase-negative staphylococci), vancomycin is recommended with rifampin for 6 weeks or more (see **Table 120–8**). An aminoglycoside is added for the first 2 weeks if the organism is aminoglycoside susceptible. For MSSA, penicillinase-resistant penicillin is administered in place of vancomycin. PVE responds poorly to medical treatment and has a higher mortality compared with native-valve endocarditis. Valve dehiscence and incompetence can result in acute heart failure, and surgery is often a component of treatment.[4,38]

Twelve months or more after valve replacement, the likely organism for PVE parallels that of native-valve endocarditis. As with native-valve endocarditis, antimicrobial therapy should be based on the identified organism and in vitro susceptibility. If an organism is identified other than staphylococci, the treatment regimen should be guided by susceptibilities and should be at least 6 weeks in duration.[4] Additionally, a concomitant aminoglycoside is recommended if streptococci or enterococci are identified. Once-daily aminoglycoside regimens have not been adequately evaluated in PVE and are not recommended.[4]

The use of anticoagulation is controversial in PVE. In general, those who require anticoagulation for a prosthetic valve should continue the anticoagulant cautiously during endocarditis therapy, unless a contraindication to therapy exists. It is recommended to hold all anticoagulation for at least 2 weeks for patients with *S. aureus* PVE if a recent central-nervous-system (CNS) embolic event has occurred.[4]

CLINICAL CONTROVERSY

Oral antibiotics for the treatment of infective endocarditis have been assessed primarily in those with IVDA. Although treating infective endocarditis with oral antibiotics would decrease adverse events associated with prolonged use of intravenous catheters, the paucity of data preclude this being a routine treatment. Oral rifampin is used as part of combination therapy in PVE caused by staphylococci. The AHA guidelines recently added ciprofloxacin orally as an option for treatment of infective endocarditis caused by the HACEK group of organisms.

ENTEROCOCCAL ENDOCARDITIS

Enterococci are normal inhabitants of the human gastrointestinal tract and, occasionally, of the anterior urethra. These organisms are usually of low virulence but can become pathogens in predisposed patients following genitourinary manipulations (older men) or obstetric procedures (younger women).[3] Historically, enterococci were considered group D streptococci, but they have been reclassified into the genus *Enterococcus (E. faecalis* and *E. faecium). E. faecalis* is the most common clinical isolate (approximately 90%) of the two species. Enterococci cause 5% to 18% of endocarditis cases, but they are more resistant to therapy than staphylococci and streptococci. Enterococci are noteworthy for these reasons: (a) no single antibiotic is bactericidal, (b) MICs to penicillin are relatively high (1 to 25 mcg/mL), (c) intrinsic resistance occurs to all cephalosporins and relative resistance occurs to aminoglycosides (e.g., "low-level" aminoglycoside resistance), (d) combinations of a cell-wall active agent such as a penicillin or vancomycin and an aminoglycoside are necessary for killing, and (e) resistance to all available drugs is increasing.[4,69,70]

Monotherapy with penicillin for infective endocarditis caused by enterococci results in relapse rates of 50% to 80%. When used alone, penicillins are only bacteriostatic against enterococci, and combination therapy is always recommended for susceptible strains.[4] The relapse rate following penicillin-gentamicin therapy for susceptible strains is less than 15%.[5] The killing of enterococci by the bactericidal combination of an aminoglycoside antibiotic and a penicillin is the best clinical example of antibiotic synergy. Because the aminoglycoside cannot penetrate the bacterial cell in the absence of the penicillin, enterococci usually will appear to be resistant to aminoglycosides by routine susceptibility testing (low-level resistance). However, in the presence of an agent that disrupts the cell wall such as penicillin, the aminoglycoside can gain

entry, attach to bacterial ribosomes, and cause rapid cell death. An aminoglycoside-vancomycin combination is also synergistic against enterococci and is appropriate therapy for the penicillin-allergic patient.[3,4]

Enterococcal endocarditis ordinarily requires 4 to 6 weeks of ampicillin or high-dose penicillin G plus an aminoglycoside for cure (Table 120–9). Ampicillin has greater in vitro activity than penicillin G, although there are no clinical data to document differences in efficacy. A 6-week course is recommended for patients with symptoms lasting longer than 3 months and those with PVE. Streptomycin has been the most extensively studied aminoglycoside, but gentamicin is presently favored. Because of resistance, other aminoglycosides, such as tobramycin and amikacin, cannot be substituted routinely. In the treatment of enterococcal endocarditis, relatively low serum concentrations of aminoglycosides appear adequate for successful therapy, such as a gentamicin peak concentration of approximately 3 to 4 mcg/mL.[4,71] Treatment of enterococcal endocarditis does not have the high success rate seen with infective endocarditis caused by viridans streptococci, presumably because the organism is more resistant to killing.

Although some data support the use of extended-interval aminoglycoside dosing for other types of endocarditis (i.e., streptococci), the data are more vague regarding this strategy in enterococcal infective endocarditis.[72] Even though some studies suggest that extended-interval aminoglycoside dosing and short-interval (traditional) dosing are clinically equivalent,[73–75] discordant studies imply otherwise.[76,77] The paucity of human data precludes routine use of extended-interval aminoglycoside dosing in this setting and the guidelines recommend three-times-daily dosing.[4]

Resistance among enterococci to penicillins and aminoglycosides is increasing.[4] Enterococci that exhibit high-level resistance to streptomycin (MIC >2000 mcg/mL) are not synergistically killed by penicillin and streptomycin because the aminoglycoside either no longer binds to the ribosome or is inactivated by an aminoglycoside-modifying enzyme, streptomycin adenylase. Because enterococci will appear resistant to aminoglycosides on routine susceptibility testing, the only way to distinguish high-level from low-level resistance is by performing special susceptibility tests using 500 to 2,000 mcg/mL of the aminoglycoside. High-level streptomycin-resistant enterococci occur with a frequency approaching 60%, and high-level resistance to gentamicin is now found in 10% to 50% of isolates. Although most gentamicin-resistant enterococci are resistant to all aminoglycosides (including amikacin), 30% to 50% remain susceptible to streptomycin.[3,69] High-level gentamicin resistance is mediated by a bifunctional aminoglycoside-modifying enzyme, 6-acetyltransferase/2-phosphotransferase, and most strains also possess streptomycin adenylase. These organisms do not commonly cause infective endocarditis; data on appropriate therapy are sparse, and therapeutic options are few.[69,70,78]

In addition to isolates with high-level aminoglycoside resistance, β-lactamase–producing enterococci (especially *E. faecium*) have been reported.[79] If these organisms are discovered, use of vancomycin or ampicillin-sulbactam in combination with gentamicin should be considered. Vancomycin-resistant enterococci are reported increasingly, primarily with *E. faecium*. Vancomycin resistance occurs when the bacterium replaces the normal vancomycin target with a peptidoglycan precursor that does not bind vancomycin.[70]

Treating multidrug-resistant enterococci is difficult, and data on appropriate therapy are sparse. Current guidelines suggest either linezolid or quinupristin-daltopristin for resistant strains of *E. faecium* and combination β-lactam therapy (ampicillin with either imipenem-cilastatin or ceftriaxone) for *E. faecalis*.[4] Daptomycin has produced conflicting results. [80–83] Surgery and replacement of the infected cardiac valve may be the only cure.

HACEK Group

Fastidious gram-negative bacteria from the HACEK group account for 5% to 10% of native-valve, community-acquired infective endocarditis.[4] Frequently, these types of infective endocarditis present as subacute illnesses with large vegetations and emboli.[3] These oropharyngeal organisms typically are slow growing and should be considered as possible causes of "culture negative" endocarditis. In the past, high-dose ampicillin with gentamicin for 4 weeks was an acceptable treatment regimen for HACEK endocarditis, but β-lactamase–producing organisms are occurring more often; hence, HACEK organisms should be considered resistant to ampicillin alone. Numerous treatments are reasonable for the treatment of HACEK infective endocarditis, including ceftriaxone and ampicillin-sulbactam; the newest addition to the guidelines is oral ciprofloxacin for select patients (Table 120–10).[4] Treatment is usually for 4 weeks, but it should be extended to 6 weeks in PVE caused by one of these organisms.

LESS-COMMON TYPES OF INFECTIVE ENDOCARDITIS

Atypical Microorganisms

Endocarditis caused by organisms such as *Bartonella; Coxiella burnetii; Brucella, Candida*, and *Aspergillus* spp.; *Legionella*; and gram-negative bacilli (e.g., *Pseudomonas*) is relatively uncommon. Medical therapy for infective endocarditis caused by these organisms is usually unsuccessful.[4,5] Consultation with an infectious disease expert is warranted when these microorganisms are identified.

In addition to *Pseudomonas* spp., other gram-negative bacilli that have been implicated include *Salmonella* spp., *Escherichia coli, Citrobacter* spp., *Klebsiella-Enterobacter* spp., *Serratia marcescens, Proteus* spp., and *Providencia* spp.[84] Generally, these infections have a poor prognosis, with mortality rates as high as 60% to 80%.[84] Cardiac surgery in concert with extended course antibacterial therapy is the recommended course (class IIa; level of evidence: B) for most patients with gram-negative bacillary infective endocarditis. Readers are referred to the AHA guidelines for more extensive review of *Pseudomonas* spp. infective endocarditis and unusual gram-negative bacteria treatment regimens.[4]

Fungi cause between 2% and 4% of endocarditis cases; most patients with fungal endocarditis have undergone recent cardiovascular surgery, are intravenous drug abusers, have received prolonged treatment with intravenous catheters or antibiotics, or are immunocompromised.[3,85] *Candida* spp. and *Aspergillus* spp. are the most commonly involved, and the mortality rate is high (greater than 80%) for these reasons: (a) large, bulky vegetations that often form, (b) systemic septic embolization that may occur, (c) the tendency for fungi to invade the myocardium, (d) poor penetration of vegetations by antifungals, (e) the low toxic-to-therapeutic ratio of agents such as amphotericin B, and (f) the lack of consistent fungicidal activity of available antifungal agents.[3,86] When fungal infective endocarditis is identified, the combined medical–surgical approach is recommended. Because these infections occur infrequently, scant clinical data are available to make solid treatment recommendations; however, the use of antifungal agents alone has been globally unsuccessful. Amphotericin B has been the mainstay pharmacologic approach. The availability of newer antifungal agents challenges this historical approach, although clinical trial data are lacking.[4]

C. burnetii (Q fever) may be recovered from blood cultures, but infection is more likely to be identified via serologic tests. It is a common cause of infective endocarditis in certain areas of the world where goat, cattle, and sheep farming are widespread.

The most favorable therapy for Q fever is unknown but may include doxycycline with trimethoprim-sulfamethoxazole, rifampin, or fluoroquinolones.[3,10] *Brucella* are facultative intracellular gram-negative bacilli. Humans are infected by this organism after ingesting infected unpasteurized milk or undercooked meat, inhalation of infectious aerosols, or contact with infected tissues. This type of infective endocarditis is more common in veterinarians and livestock handlers. Cure requires valve replacement and antimicrobial agents including doxycycline with streptomycin or gentamicin or doxycycline with trimethoprim-sulfamethoxazole or rifampin for an extended period (8 weeks to months).[10]

Culture-Negative Endocarditis

Sterile blood cultures are reported in 5% to 20% of patients with infective endocarditis if strict diagnostic criteria are used.[5,12] This type of infective endocarditis may occur as a result of unidentified subacute right-sided infective endocarditis, previous antibiotic therapy, slow-growing fastidious organisms, nonbacterial etiologies (e.g., fungi), and improperly collected blood cultures. When blood cultures from patients suspected of infective endocarditis show no growth after 48 to 72 hours, the laboratory should be advised, and cultures should be held for up to a month to detect growth of fastidious organisms.[4]

The AHA guidelines provide general recommendations for culture-negative infective endocarditis (Table 120–11), although clinicians should individualize therapy, as necessary. Selection of treatment can be difficult, balancing the need to cover all likely organisms against potential toxic drug effects (e.g., aminoglycosides). Antimicrobial selection should be in consultation with an infectious diseases specialist. Irrespective of the chosen treatment, extended antimicrobial therapy is required. The preceding empirical approaches for culture-negative infective endocarditis highlight the need for proper collection and monitoring of blood cultures and an extensive medication history.

PHARMACOECONOMIC CONSIDERATIONS

Infective endocarditis remains an uncommon disease, but the cost of treatment can be substantial. In the past, the long duration of hospitalization required to administer intravenous antimicrobials was the major expense. In select cases, abbreviated and/or outpatient, oral antimicrobial therapy may appreciably reduce the cost of care.

Shorter-course antimicrobial regimens are advocated when possible. For instance, in exquisitely sensitive streptococcal endocarditis (MICs less than 0.12 mcg/mL), a 2-week regimen of high-dose parenteral penicillin G or ceftriaxone in combination with an aminoglycoside is as effective as 4 weeks of penicillin alone.[4] Uncomplicated right-sided MSSA endocarditis in the intravenous drug abuser may be treated with a 2-week course. Treatment with nafcillin or oxacillin in combination with an aminoglycoside appears to be cost-effective.

The initiation of outpatient parenteral antibiotics should be considered early in the treatment of infective endocarditis, after the patient is stable clinically and responds favorably to initial antibiotics. Outpatient treatment is safe and cost-effective in select situations.[22,87] Patients considered for home therapy must be hemodynamically stable, compliant with therapy, have careful medical monitoring, understand the potential complications of the disease, and have immediate access to medical care. Advances in technology allow for the outpatient administration of complex antibiotic regimens that significantly reduce the cost of therapy. Simple regimens, such as single daily doses of ceftriaxone for streptococcal infective endocarditis, are particularly attractive. Although endocarditis is common in those with a history of IVDA and home healthcare would substantially reduce the cost of treatment, many clinicians are uncomfortable with outpatient intravenous therapy because central venous access is required. Sudden cardiac decompensation in an outpatient setting is also of concern.[4,88]

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of patients treated for infective endocarditis includes assessment of disease signs and symptoms, blood cultures, microbiologic tests, serum drug concentrations, and other tests that evaluate organ function.

SIGNS AND SYMPTOMS

Fever usually subsides within 1 week of initiating therapy.[1,5,88] Persistence of fever may indicate ineffective antimicrobial therapy, emboli, infections of intravascular catheters, or drug reactions. For some patients, low-grade fever may persist even with appropriate antimicrobial therapy. With defervescence, the patient should begin to feel better, and other symptoms, such as lethargy or weakness, should subside. Echocardiography should be performed when antibiotic therapy has been completed to determine new baseline cardiac function (i.e., ventricular size and function). A TTE is usually sufficient.

BLOOD CULTURES

Blood cultures should be negative within a few days, although microbiologic response to vancomycin may be slower. If bacteria continue to be isolated from blood beyond the first few days of therapy, it may indicate that the antimicrobials are inactive against the pathogen or that the doses are not producing adequate concentrations at the site of infection. After the initiation of therapy, blood cultures should be rechecked until negative. During the remainder of therapy, frequent blood culturing is not necessary. Additional blood cultures should be rechecked after successful treatment (e.g., once or twice within the 8 weeks after treatment) to ensure cure.[4]

MICROBIOLOGIC TESTS

For all isolates from blood cultures, MICs should be determined; MBCs are no longer recommended.[4] The agent currently being used should be tested, as well as alternatives that may be required if intolerance, allergy, or resistance occurs. Occasionally, it is useful to determine whether synergy exists for antimicrobial combinations, although synergistic regimens usually can be predicted from the literature. Chapter 113 summarizes the methods for in vitro determinations of synergy.

Serum bactericidal titers (SBTs; also called *Schlichter tests*) have been used in the past in association with a number of infectious diseases. The SBT is the greatest dilution of a patient's serum sample that is obtained while receiving antimicrobial treatment that kills greater than 99.9% of an inoculum of the infecting pathogen in vitro over 18 to 24 hours.

Although specific SBTs have been evaluated in endocarditis, at present, SBTs have little value in monitoring treatment of common types of infective endocarditis and should not be recommended routinely.[4,89] This test may be useful when the causative organisms are only moderately susceptible to antimicrobials, when less-well-established regimens are used, or when response to therapy is suboptimal and dosage escalation is being considered.

SERUM DRUG CONCENTRATIONS

Of the agents used commonly for infective endocarditis, measurement of serum drug concentrations is routinely available for aminoglycosides (except streptomycin) and vancomycin. Few data, however, support attaining any specific serum concentrations for patients with infective endocarditis. In general, serum concentrations of the antimicrobial should exceed the MBC of the organisms. Aminoglycoside concentrations rarely exceed the MBC for certain organisms, such as streptococci and enterococci, and concentrations of aminoglycosides and vancomycin for staphylococci have not been correlated with response.[89,90]

When aminoglycosides are administered for infective endocarditis caused by gram-positive cocci with a traditional three-times-daily regimen, peak serum concentrations are recommended to be on the low side of the traditional ranges (3 to 4 mcg/mL for gentamicin). If extended-interval dosing is used, which is only recommended in streptococcal infective endocarditis, the most appropriate method of monitoring has not been determined. When vancomycin is administered, the most recent treatment guidelines for infective endocarditis recommend serum drug monitoring of peak and trough concentrations.[4] However, it is now generally accepted that peak concentrations of vancomycin have limited clinical applicability and the primary goal of serum vancomycin monitoring is to ensure adequate trough concentrations, in this case 15 to 20 mcg/mL, are achieved.[4,91]

PREVENTION

⑩ Antimicrobial prophylaxis is used as an attempt to prevent infective endocarditis for patients who are at the highest risk.[6,15] The use of antimicrobials for this purpose requires consideration of (a) cardiac conditions associated with endocarditis, (b) procedures causing bacteremia, (c) organisms likely to cause endocarditis, and (d) pharmacokinetics, spectrum, cost, adverse effects, and ease of administration of available antimicrobial agents. The objective of prophylaxis is to diminish the likelihood of infective endocarditis in high-risk individuals from procedures that result in bacteremia. Although there are no prospective, controlled human trials demonstrating that prophylaxis in high-risk individuals protects against the development of endocarditis during bacteremia-induced procedures, animal studies suggest possible benefit.[15] Many causes of infective endocarditis, however, appear not to be secondary to an invasive procedure. Bacteremia as a consequence of daily activities may, in fact, be the major culprit, and the value of antibiotic prophylaxis before bacteremia-causing procedures has been questioned.[92] Retrospective human studies, though, support that a reduction of endocarditis occurs for select patients following dental surgery where prophylaxis is employed.[15] The common practice of using antimicrobial therapy in this setting remains controversial. The mechanism of a beneficial effect in humans is unclear, but antibiotics may decrease the number of bacteria at the surgical site, kill bacteria after they are introduced into the blood, and prevent adhesion of bacteria to the valve. Prophylaxis does not reduce the frequency of bacteremia immediately following tooth extraction as compared with a control group, suggesting that a reduction in adhesion or effects after the bacteria adhere to the endocardium are more likely mechanisms.[93,94] Other studies have further questioned the benefit of antibiotic prophylaxis.[95]

Regardless of the controversy about whether prophylactic antibiotics should be used, infective endocarditis prophylaxis is recommended in select situations, specifically dental procedures, in those with underlying high-risk cardiac conditions. Recently the AHA released new guidelines that better define who should and should not receive infective endocarditis prophylaxis.[15] This update is timely as data show overuse of infective endocarditis prophylaxis occurs in low-risk patients and underuse occurs in those at greater risk.[96]

TABLE 120-12 Cardiac Conditions Associated with the Highest Risk of Adverse Outcome from Endocarditis for Which Prophylaxis with Dental Procedures is Recommended

Prosthetic cardiac valves
Previous infective endocarditis
Congenital heart disease (CHD)[a]
Unrepaired cyanotic CHD, including palliative shunts and conduits
Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure[b]
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (that inhibit endothelialization)
Cardiac transplantation recipients who develop cardiac valvulopathy

[a]Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.
[b]Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.

CLINICAL CONTROVERSY

The common practice of administering antibiotics to high-risk individuals before a bacteremia-causing procedure is controversial. Despite limited data supporting this approach and the fact that 100% compliance with AHA preventative guidelines would have only a modest benefit, the use of single-dose antibiotics for the prevention of endocarditis remains a standard of care.

Key points of this report are that (a) only a small number of cases of infective endocarditis might be prevented with antibiotic prophylaxis for dental procedures, even if 100% effective; (b) infective endocarditis prophylaxis for dental procedures should be recommended only for patients with underlying cardiac conditions associated with the highest risk; (c) for those with high-risk underlying cardiac conditions, prophylaxis is recommended for all dental procedures involving manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa; (d) prophylaxis is not recommended based solely on an increased lifetime risk of acquisition of infective endocarditis; and (e) administration of antibiotics solely to prevent endocarditis is not recommended for patients who undergo a genitourinary or gastrointestinal tract procedure.

To determine whether a patient should receive prophylactic antibiotics, one needs to assess the patient's risk (Table 120–12) and whether they are undergoing a procedure resulting in bacteremia (Table 120–13). When antibiotic prophylaxis is appropriate,

TABLE 120-13 Dental Procedures for Which Endocarditis Prophylaxis Is Recommended for Patients Described in Table 120–12

All dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa[a]

[a]The following procedures and events do not need prophylaxis: routine anesthetic injections through noninfected tissue, taking dental radiographs, placement of removable prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to the lips or oral mucosa.
From reference 4, with permission. Copyright 2005, American Medical Association.

TABLE 120-14 Antibiotic Regimens for a Dental Procedure

Situation	Agent	Regimen: Single Dose 30 to 60 Minutes Before Procedure	
		Adults	***Children***
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin	2 g IM or IV	50 mg/kg IM or IV
	or		
	Cefazolin or ceftriazone	1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillins or ampicillin (oral)	Cephalexin[a,b]	2 g	50 mg/kg
	or		
	Clindamycin	600 mg	20 mg/kg
	or		
	Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone[b]	1 g IM or IV	50 mg/kg IM or IV
	or		
	Clindamycin	600 mg IM or IV	20 mg/kg IM or IV

[a]Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.
[b]Cephalosporins should not be used for an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.
From reference 4, with permission. Copyright 2005, American Medical Association.

a single 2 g dose of amoxicillin is recommended for adult patients at risk, given 30 to 60 minutes before undergoing procedures associated with bacteremia (Table 120–14). Because the duration of antimicrobial prophylaxis appears to be relatively short, these guidelines do not advocate a second oral dose of amoxicillin, which was recommended previously. Alternative prophylaxis regimens for patients allergic to penicillins or those unable to take oral medications are also provided.

ABBREVIATIONS

AHA: American Heart Association

HACEK: The group of bacteria including *Haemophilus parainfluenzae, Haemophilus aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*

IVDA: intravenous drug abuse

MBC: minimal bactericidal concentration

MIC: minimal inhibitor concentration

MRSA: methicillin-resistant *Staphylococcus aureus*

MSSA: methicillin-sensitive *Staphylococcus aureus*

PVE: prosthetic valve endocarditis

SBT: serum bactericidal titer

TEE: transesophageal echocardiogram

TTE: transthoracic echocardiogram

CHAPTER 121

Tuberculosis

CHARLES A. PELOQUIN AND ROCSANNA NAMDAR

KEY CONCEPTS

1. Tuberculosis (TB) is the most prevalent communicable infectious disease on earth; it remains out of control in many developing nations. These nations require medical and financial assistance from developed nations in order to control the spread of TB globally.
2. In the United States, TB disproportionately affects ethnic minorities as compared with whites, reflecting greater ongoing transmission in ethnic minority communities. Additional TB surveillance and preventive treatment are required within these communities.
3. Coinfection with human immunodeficiency virus (HIV) and TB accelerates the progression of both diseases, thus requiring rapid diagnosis and treatment of both diseases.
4. Mycobacteria are slow-growing organisms; in the laboratory, they require special stains, special growth media, and long periods of incubation to isolate and identify.
5. TB can produce atypical signs and symptoms in infants, the elderly, and immunocompromised hosts, and it can progress rapidly in these patients.
6. Latent TB infection (LTBI) can lead to reactivation disease years after the primary infection occurred.
7. The patient suspected of having active TB disease must be isolated until the diagnosis is confirmed and the patient is no longer contagious. Often, isolation takes place in specialized "negative-pressure" hospital rooms to prevent the spread of TB.
8. Isoniazid and rifampin are the two most important TB drugs; organisms resistant to both these drugs [multidrug-resistant TB (MDR-TB)] are much more difficult to treat.
9. Never add a single drug to a failing TB treatment regimen!
10. Directly observed treatment should be used whenever possible to reduce treatment failures and the selection of drug-resistant isolates.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Tuberculosis (TB) remains a leading infectious killer globally. TB is caused by *Mycobacterium tuberculosis*, which can produce either a silent, latent infection or a progressive, active disease.[1] Left untreated or improperly treated, TB causes progressive tissue destruction and, eventually, death. Because of renewed public health efforts, TB rates in the United States continue to decline. In contrast, TB remains out of control in many developing countries—to the point that one-third of the world's population currently is infected.[1] Given increasing drug resistance, it is critical that a major effort be made to control TB before the most effective drugs are lost permanently.

M. tuberculosis preferentially infects humans, and the closely related *Mycobacterium bovis* causes a similar disease in cattle and other livestock. Although uncommon today, humans frequently developed TB by drinking milk contaminated with *M. bovis*— a threat that spurred the development of pasteurization. Today, airborne *M. tuberculosis* is the main threat to humans.

Evidence of TB has been found in ancient human remains, and ancient texts describe it.[1–3] TB commonly was known as "consumption" because of the pronounced weight loss that it caused.[1] Other common names included "wasting disease" and the "white plague." As the term *plague* implies, TB had a profound impact on human history, most notably in Europe. (Note: The "black plague," or bubonic plague, is a separate disease caused by *Yersinia pestis*.)

TB rates generally have risen with increasing urbanization and overcrowding because it is easier for an airborne disease to spread when people are packed closely together.[3] Hence TB became a significant pathogen in Europe during the Middle Ages and peaked during the Industrial Revolution, when it caused approximately 25% of all deaths in Europe and in the United States.[1–3] This dire threat led to the rise of public health departments and to procedures such as the isolation of infected patients. Thus, TB was directly responsible for many of the healthcare practices that we take for granted today. Unfortunately, in developing nations, some of these practices are not widely available, and TB continues to rage unabated.

EPIDEMIOLOGY

Globally, roughly 2 billion people are infected by *M. tuberculosis*, and roughly 2 million people die from active TB each year despite the fact that it is curable.[1,2,4] In the United States, about 13 million people are latently infected with *M. tuberculosis*, meaning that they are not currently sick but that they could fall ill with TB at any time. The United States had 12,904 new cases of active TB in 2008 and about 644 deaths in 2006.[5] [For detailed data analysis, visit the Centers for Disease Control and Prevention (CDC) website at *www.cdc.gov/nchstp/tb*.)] The annual incidence of TB in the United States declined by approximately 5% per year from 1953 to 1983[6]

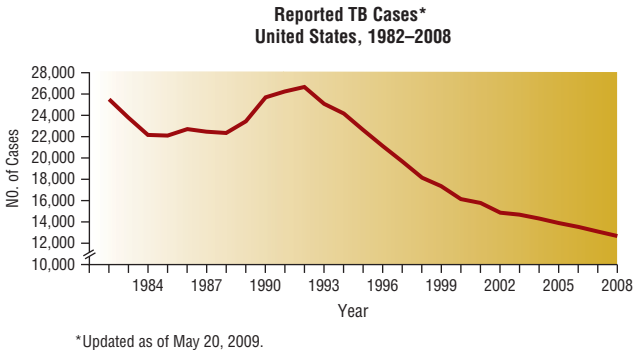

FIGURE 121-1. Reported tuberculosis cases in the United States, 1982 to 2008. *(From the Centers for Disease Control and Prevention. www.cdc.gov.)*

(Fig. 121–1). In 1984, this decline slowed, and then the incidence of TB rose from 1988 to 1992, reaching 10.5 cases per 100,000 population. Since 1992, more effective infection control practices and treatment protocols have reduced TB rates to 4.2 per 100,000 population as of 2008.[5] Despite this good news, the eradication of TB from the United States remains very difficult. One reason is that we continue to import new cases from countries where TB remains out of control.[4,5]

RISK FACTORS FOR INFECTION

Location and Place of Birth

TB can infect anyone, but the risk is not evenly distributed across the U.S. population. The major points of entry into the United States have the most TB cases. Four states (California, Florida, New York, and Texas) reported more than 500 cases each for 2008; combined, these four states accounted for 49% (6,350 cases) of the national total.[5] Within these states, TB is most prevalent in large urban areas.[4]

The TB rate among foreign-born persons was 10 times that of U.S.-born persons in 2008.[5] The percentage of foreign-born TB patients in the United States has increased annually since 1986, reaching 59% in 2008.[5] More than half (59.0%) of the foreign-born cases in 2008 were reported in persons from Mexico (1,752), the Philippines (855), Vietnam (582), India (596), and China (398).[5] Therefore, healthcare workers must "think TB" when caring for patients from these countries who experience symptoms such as cough, fever, and weight loss.

Close contacts of pulmonary TB patients are most likely to become infected.[2–4] These include family members, coworkers, or coresidents in places such as prisons, shelters, or nursing homes. The more prolonged the contact, the greater is the risk, with infection rates as high as 30%.[5,6] Although many circumstances exist, TB patients frequently have limited access to healthcare, live in crowded conditions, or are homeless.[2,4] Many patients have histories of alcohol abuse or illicit drug use, and many are coinfected with hepatitis B or human immunodeficiency virus (HIV). These concurrent social and health problems make treating some TB patients particularly difficult.

Race, Ethnicity, Age, and Gender

2 In the United States, TB disproportionately affects ethnic minorities. Hispanics, blacks, and Asians had TB rates 7.4, 8.0, and 23.2 times, respectively, higher than whites in 2008.[5] Hispanics accounted for 29% of all TB cases, followed by Asians at 26%[5] and blacks accounted for 25%, whereas non-Hispanic whites accounted for only 17% of the new TB cases.[5]

TB is most common among people 25 to 44 years of age (33% of all U.S. cases in 2008), followed by those 45 to 64 years of age (30%) and 65 years of age and older (19%).[5] TB is more common in older whites and Asians compared with younger people from these groups. This reflects reactivation of latent infection acquired many years earlier when TB was very common. Older blacks and Hispanics also have more TB than younger individuals, but the differences by age are not as pronounced.[5] This reflects a greater recent transmission among younger blacks and Hispanics compared with younger whites and Asians. Until the age of 15 years, TB rates are similar for males and females, but after that, the male predominance increases with each decade of life.[5]

Coinfection with Human Immunodeficiency Virus

3 HIV is the most important risk factor for active TB, especially among people 25 to 44 years of age.[2,4,5,7] TB and HIV seem to act synergistically within patients and across populations, making each disease worse than it might otherwise be. *Approximately 6% of U.S. TB patients are coinfected with HIV, and 10% of TB patients ages 25 to 44 years are coinfected.*[5] These numbers are estimates because laws and regulations in some states prohibit sharing HIV status of TB patients with the TB program. HIV coinfection may not increase the risk of acquiring *M. tuberculosis* infection, but it does increase the likelihood of progression to active disease.[1,7] There is evidence for higher mortality rates in HIV coinfected with MDR and XDR-TB.[8] Furthermore, TB and HIV patients share a number of behavioral risk factors that contribute to the high rates of coinfection.[2,9,10]

RISK FACTORS FOR DISEASE

Once infected with *M. tuberculosis*, a person's lifetime risk of active TB is approximately 10%.[2,4,7] The greatest risk for active disease occurs during the first 2 years after infection. Children younger than 2 years of age and adults older than 65 years of age have two to five times greater risk for active disease compared with other age groups. Patients with underlying immune suppression (e.g., renal failure, cancer, and immunosuppressive drug treatment) have 4 to 16 times greater risk than other patients. Finally, HIV-infected patients with *M. tuberculosis* infection are 100 times more likely to develop active TB than normal hosts.[4,11] HIV-infected patients have an annual risk of active TB of approximately 10%, rather than a lifetime risk at that rate. Therefore, all patients with HIV infection should be screened for tuberculous infection, and those known to be infected with *M. tuberculosis* should be tested for HIV infection.

ETIOLOGY

M. tuberculosis is a slender bacillus with a waxy outer layer.[2,7] It is 1 to 4 μm in length, and under the microscope, it is either straight or slightly curved in shape.[1,12,13] It does not stain well with Gram stain, so the Ziehl-Neelsen stain or the fluorochrome stain must be used instead.[1,2,7] After Ziehl-Neelsen staining with carbol-fuchsin, mycobacteria retain the red color despite acid–alcohol washes. Hence, they are called *acid-fast bacilli*.[12] After staining, microscopic examination ("smear") detects about 8,000 to 10,000 organisms per milliliter of specimen, so a patient can be "smear negative" but still grow *M. tuberculosis* on culture. Microscopic examination also can not determine which of the more than 100 mycobacterial species is present or whether the organisms in the original samples were alive or dead.[1,12,13] On smear, they are all dead. On culture, *M. tuberculosis* grows slowly, doubling about every 20 hours. This is slow compared

with gram-positive and gram-negative bacteria, which double about every 30 minutes.

Among the mycobacteria, only *M. tuberculosis* is a frequent human pathogen. Some nontuberculous mycobacteria such as *Mycobacterium kansasii, Mycobacterium fortuitum*, and *Mycobacterium avium* complex (MAC) cause infections in patients with other medical problems, especially the acquired immunodeficiency syndrome (AIDS). The treatment of these infections is discussed in Chap. 134.

CULTURE AND SUSCEPTIBILITY TESTING

4 Direct susceptibility testing involves inoculating specialized media with organisms taken directly from a concentrated, smear-positive specimen.[1,12,13] This approach produces susceptibility results in 2 to 3 weeks. Indirect susceptibility testing involves inoculating the test media with organisms obtained from a pure culture of the organisms, which can take several more weeks. The most common agar method, known as the *proportion method,* uses the ratio of colony counts on drug-containing agar to that on drug-free agar.[1,13] In the United States, the critical proportion for resistance is 1%. That means that if a drug-containing plate shows only 2% of the growth seen on a drug-free plate, some of the organisms from the specimen were resistant to that drug. Therefore, it is likely that many of the organisms in the patient also are resistant to that drug, and it should not be used to treat that patient.

The proportion method's limitations include many weeks to obtain results, drug degradation during the incubation, and a qualitative result (susceptible or resistant). The BACTEC system (Becton-Dickinson, Sparks, MD) uses liquid medium (7H12 broth) and detects live mycobacteria based on the release of radiolabeled CO_2.[12] Advantages of the BACTEC system include reduced incubation time (as few as 9 to 14 days), reduced drug loss in the medium, and when multiple concentrations are tested, a truly quantitative end point [minimal inhibitory concentration (MIC)].[1,12,13] Newer, nonradiometric rapid methods such as the MGIT system are now being used by many laboratories.[14]

Rapid-identification tests are now available.[14] Nucleic acid probes such as the AccuProbe (Gen-Probe, San Diego, CA) use DNA probes to identify the presence of complementary ribosomal ribonucleic acid (rRNA) for several mycobacterial species.[7,12,15] DNA fingerprinting using restriction-fragment-length polymorphism analysis has been used to identify clusters of cases.[1,12,15] Amplification of the genetic material can be achieved through polymerase chain reaction (Roche Molecular Systems, Branchburg, NJ), the amplified *M. tuberculosis* direct (MTD) test (Gen-Probe, San Diego, CA), and strand-displacement amplification (SDA; Becton-Dickinson, Sparks, MD).[12,16] Thin-layer chromatography, high-performance liquid chromatography for mycolic acid identification, and gas chromatography for short-chain fatty acids (methyl esters) have been used to speciate mycobacterial isolates.[1,12,15] Other tests are designed to detect common genetic changes associated with drug resistance, such as changes in the *katG* gene associated with isoniazid resistance and the *rpoB* gene associated with rifampin resistance.[7,17–19] One such test, the Hain test, is being evaluated by the FDA and has entered into limited clinical use in the United States. These tests offer clinicians a chance to know rapidly what organism they are treating and what drugs might be good initial choices.

TRANSMISSION

M. tuberculosis is transmitted from person to person by coughing or sneezing.[2,7,14] This produces "droplet nuclei" that are dispersed in the air. Each droplet nuclei contains one to three organisms. Riley and colleagues showed that air circulated from a hospital TB ward could cause disease in guinea pigs.[20] When this air was filtered or treated with ultraviolet radiation, the animals were not infected. Approximately 30% of individuals who experience prolonged contact with an infectious TB patient will become infected.

A person with cavitary, pulmonary TB and a cough may infect roughly one person per month until that person is treated effectively, although this number can vary significantly. A person with the uncommon laryngeal form of TB can spread organisms even when talking, so the transmission rates can be very high. HIV-infected patients acquire the organisms through the lungs just like normal hosts, but their weakened immune system puts them at very high risk for active disease.[2,4,7,14]

PATHOPHYSIOLOGY

IMMUNE RESPONSE

Good T-lymphocyte responses are essential to controlling *M. tuberculosis* infections.[2,7,21,22] In the mouse model, two different T-cell responses—the T-helper type 1 (TH_1) response and the T-helper type 2 (TH_2) response—have been described. The TH_1 response is the preferred response to TB, and the TH_2 response, including the potentially subversive influence of interleukin (IL) 4, is undesirable.[2,21,22] Some workers have argued that this dichotomy is clearer in the mouse model, and in many humans, the T-cell response may be classified as TH_0 (elements of both TH_1 and TH_2).[21] In either case, T lymphocytes activate macrophages that, in turn, engulf and kill mycobacteria. T lymphocytes also destroy immature macrophages that harbor *M. tuberculosis* but are unable to kill the invaders.[21,22] CD4+ cells are the primary T cells involved, with contributions by γδ T cells and CD8+ T cells.[20] CD4+ T cells produce interferon- γ (INF-γ) and other cytokines, including IL-2 and IL-10, that coordinate the immune response to TB.[21] Because CD4+ cells are depleted in HIV-infected patients, these patients are unable to mount an adequate defense to TB.[21,22]

Although B-cell responses and antibody production can be demonstrated in TB-infected mammals, these humoral responses do not appear to contribute much to the control of TB within the host.[2,7,21] T cells are responding to certain mycobacterial antigens, but the key antigen(s) invoking the immune response have not been identified.[21] Tumor necrosis factor-α (TNF-α) and INF-γ are important cytokines involved in coordinating the host's cell-mediated response. Rheumatoid arthritis patients treated with TNF-α inhibitors (such as infliximab) have high rates of reactivation TB.[23] Therefore, patients known to be deficient in the activity of TNF-α or INF-γ should be screened for TB infection and offered appropriate treatment.

M. tuberculosis has several ways of evading or resisting the host immune response.[21,22] In particular, *M. tuberculosis* can inhibit the fusion of lysosomes to phagosomes inside macrophages. This prevents the destructive enzymes found in the lysosomes from getting to the bacilli captured in the phagosomes. This inhibition of destructive mechanisms allows time for *M. tuberculosis* to escape into the cytoplasm. Virulent *M. tuberculosis* is able to multiply in the macrophage cytoplasm, thus perpetuating their spread. Finally, lipoarabinomannan (LAM), the principal structural polysaccharide of the mycobacterial cell wall, inhibits the host immune response.[21,22] Lipoarabinomannan induces immunosuppressive cytokines, thus blocking macrophage activation; additionally, lipoarabinomannan scavenges O_2, thus preventing attack by superoxide anions, hydrogen peroxide, singlet oxygen, and hydroxyl radicals.[21,22] These survival mechanisms make *M. tuberculosis* a particularly difficult organism to control. Any defects in the host immune system make

it likely that *M. tuberculosis* will not be controlled and that active disease will ensue.

PRIMARY INFECTION

Primary infection usually results from inhaling airborne particles that contain *M. tuberculosis*.[2,7,22] These particles, called *droplet nuclei,* contain one to three bacilli and are small enough (1 to 5 mm) to reach the alveolar surface. Ingestion (swallowing) and inoculation (puncture wound) are other rare pathways to acquire *M. tuberculosis* infection.[22]

The progression to clinical disease depends on three factors: (a) the number of *M. tuberculosis* organisms inhaled (infecting dose), (b) the virulence of these organisms, and (c) the host's cell-mediated immune response.[2,5,7,14,22,24] At the alveolar surface, the bacilli that were delivered by the droplet nuclei are ingested by pulmonary macrophages.[22] If these macrophages inhibit or kill the bacilli, infection is aborted.[22] If the macrophages cannot do this, the organisms continue to multiply. The macrophages eventually rupture, releasing many bacilli, and these mycobacteria are then phagocytized by other macrophages. This cycle continues over several weeks until the host is able to mount a more coordinated response.[22] During this early phase of infection, *M. tuberculosis* multiplies logarithmically.[22]

Some of the intracellular organisms are transported by the macrophages to regional lymph nodes in the hilar, mediastinal, and retroperitoneal areas. The cycle of phagocytosis and cell rupture continues. During lymph node involvement, the mycobacteria may be held in check. More frequently, *M. tuberculosis* spreads throughout the body through the bloodstream.[2,7,22] When this intravascular dissemination occurs, *M. tuberculosis* can infect any tissue or organ in the body. Most commonly, *M. tuberculosis* infects the posterior apical region of the lungs. This may be so because of the high oxygen content, and it may be because of a less vigorous immune response in this area.

After about 3 weeks of infection, T lymphocytes are presented with *M. tuberculosis* antigens. These T cells become activated and begin to secrete INF-γ and the other cytokines noted earlier. The processes described in the immune response section earlier then begin to occur. First, T-lymphocytes stimulate macrophages to become bactericidal.[22] Large numbers of activated microbicidal macrophages surround the solid caseous (cheese-like) tuberculous foci (the necrotic area of infection).[22] This process of creating activated microbicidal macrophages is known as *cell-mediated immunity* (CMI).[22]

At the same time that cell-mediated immunity occurs, delayed-type hypersensitivity also develops through the activation and multiplication of T lymphocytes. Delayed-type hypersensitivity (DTH) refers to the cytotoxic immune process that kills nonactivated immature macrophages that are permitting intracellular bacillary replication.[22] These immature macrophages are killed when the T lymphocytes initiate Fas-mediated apoptosis (programmed cell death).[22] The bacilli released from the immature macrophages then are killed by the activated macrophages.[22]

By this time (>3 weeks), macrophages have begun to form granulomas to contain the organisms. In a typical tuberculous granuloma, activated macrophages accumulate around a caseous lesion and prevent its further extension.[22] At this point, the infection is largely under control, and bacillary replication falls off dramatically. Depending on the inflammatory response, tissue necrosis and calcification of the infection site plus the regional lymph nodes may occur.

Over 1 to 3 months, activated lymphocytes reach an adequate number, and tissue hypersensitivity results. This is shown by a positive tuberculin skin test. Any remaining mycobacteria are believed to reside primarily within granulomas or within macrophages that have avoided detection and lysis, although some residual bacilli have been found in various types of cells.[2,7,21]

Approximately 90% of infected patients have no further clinical manifestations. Most patients only show a positive skin test (70%), whereas some also have radiographic evidence of stable granulomas (approximately 20%). This radiodense area on chest radiograph is called a *Ghon complex*. Approximately 5% of patients (usually children, the elderly, and the immunocompromised) experience "progressive primary" disease that occurs before skin test conversion.[25,26] This presents as a progressive pneumonia, usually in the lower lobes. Disease frequently spreads, leading to meningitis and other severe forms of TB.[25,26] Because of this risk of severe disease, very young, elderly, and immunocompromised patients, including those with HIV, should be evaluated and treated for latent or active TB.

REACTIVATION DISEASE

6 Roughly 10% of infected patients develop reactivation disease at some point in their lives. Nearly half of these cases occur within 2 years of infection.[2,7,14] In the United States, most cases of TB are believed to result from reactivation. Reinfection is uncommon in the United States because of the low rate of exposure and because previously sensitized individuals possess some degree of immunity to reinfection.[2,22] Exceptions include patients coinfected with HIV who live in areas of higher exposure to *M. tuberculosis.*

The apices of the lungs are the most common sites for reactivation (85% of cases).[2] This reflects the fact that *M. tuberculosis* prefers areas with high oxygen content and possibly because the immune response may not be as effective in this region.[2,22] For reasons that are not entirely known (waning cellular immunity, loss of specific T-cell clones, blocking antibody), organisms within granulomas emerge and begin multiplying extracellularly.[22] The inflammatory response produces caseating granulomas, which eventually will liquefy and spread locally, leading to the formation of a hole (cavity) in the lungs.

The immune response contributes to the severity of the lung damage. There is targeted killing of immature macrophages that are allowing mycobacterial multiplication (DTH).[21,22] In addition, there is "innocent bystander" killing of host cells and locally thrombosed blood vessels.[22] The killing of mycobacteria, macrophages, and neutrophils that have entered the battle releases cytokines and lysozymes into the infectious foci. This toxic mixture can be too much for the surrounding alveoli and airway cells, causing regional necrosis and structural collapse.[2,22] These unstable foci liquefy, spreading the infection to neighboring areas of the lung, creating a cavity. Some of this necrotic material is coughed out, producing droplet nuclei. Bacterial counts in the cavities can be as high as 10^8 per milliliter of cavitary fluid. Partial healing may result from fibrosis, but these lesions remain unstable and may continue to expand.[2,22] If left untreated, pulmonary TB continues to destroy the lungs, resulting in hypoxia, respiratory acidosis, and eventually death.

EXTRAPULMONARY AND MILIARY TUBERCULOSIS

Caseating granulomas at extrapulmonary sites can undergo liquefaction, releasing tubercle bacilli and causing symptomatic disease.[2,7] Extrapulmonary TB without concurrent pulmonary disease is uncommon in normal hosts but more common in HIV-infected patients. Because of these unusual presentations, the diagnosis of TB is difficult and often delayed in immunocompromised hosts.[2,4,7] Lymphatic and pleural diseases are the most common forms of

extrapulmonary TB, followed by bone, joint, genitourinary, meningeal, and other forms.[2,7] Left untreated, these forms will spread to other organs and may result in death.

Occasionally, a massive inoculum of organisms enters the bloodstream, causing a widely disseminated form of the disease known as *miliary TB*. It is named for the millet seed appearance of the small granulomas seen on chest radiographs, and it can be rapidly fatal.[21] Miliary TB is a medical emergency requiring immediate treatment.

INFLUENCE OF HIV INFECTION ON PATHOGENESIS

3 HIV infection is the largest risk factor for active TB.[2,7,21] As CD4+ lymphocytes multiply in response to the mycobacterial infection, HIV multiplies within these cells and selectively destroys them. In turn, the TB-fighting lymphocytes are depleted.[21] This vicious cycle puts HIV-infected patients at 100 times the risk of active TB compared with HIV-negative people.[27] In addition, the combination of HIV infection and certain social behaviors increases the risk of newly acquired TB. In select areas of the United States, up to 50% of new TB cases are the result of recent infection, particularly among HIV-infected individuals.[27–29]

As mycobacteria spread throughout the body, HIV replication accelerates in lymphocytes and macrophages. This leads to progression of HIV disease.[21,30] HIV-infected patients who are infected with TB deteriorate more rapidly unless they receive antimycobacterial chemotherapy.[31,32] Most clinicians now recommend beginning TB treatment first, and 2 weeks later, begin HIV treatment. Some patients will experience paradoxical worsening of the TB.[14,33] This appears to result from a reinvigorated inflammatory response to TB. Because TB can be very dangerous in HIV-positive patients, they should be screened for tuberculous infection or disease soon after they are shown to be HIV-positive.[2,4,7,21]

CLINICAL PRESENTATION

The classical presentation of TB is shown below. The onset of TB may be gradual, and the diagnosis may not be considered until a chest radiograph is performed. Unfortunately, many patients do not seek medical attention until more dramatic symptoms, such as hemoptysis, occur. At this point, patients typically have large cavitary lesions in the lungs. These cavities are loaded with *M. tuberculosis*.

CLINICAL PRESENTATION OF TUBERCULOSIS

Signs and Symptoms

- Patients typically present with weight loss, fatigue, a productive cough, fever, and night sweats.[1,2,7,24]
- Frank hemoptysis.

Physical Examination

- Dullness to chest percussion, rales, and increased vocal fremitus are observed frequently on auscultation.

Laboratory Tests

- Moderate elevations in the white blood cell (WBC) count with a lymphocyte predominance.

Chest Radiograph

- Patchy or nodular infiltrates in the apical areas of the upper lobes or the superior segment of the lower lobes.[2,7,24]
- Cavitation that may show air-fluid levels as the infection progresses.

Expectoration or swallowing of infected sputum may spread the disease to other areas of the body.[1,2,7,24] Physical examination is nonspecific but suggestive of progressive pulmonary disease.

5 Patients coinfected with HIV may have atypical presentations.[1,2,7,24,34] As their CD4+ counts decline, HIV-positive patients are less likely to have positive skin tests, cavitary lesions, or fever. Pulmonary radiographic findings may be minimal or absent. HIV-positive patients have a higher incidence of extrapulmonary TB and are more likely to present with progressive primary disease. Because their symptoms are not specific to TB, a thorough workup for TB is essential.[2,7,21,24]

Extrapulmonary TB typically presents as a slowly progressive decline in organ function.[2,7,24] Patients may have low-grade fever and other constitutional symptoms. Patients with genitourinary TB may present with sterile pyuria and hematuria. Lymphadenitis often involves the cervical and supraclavicular nodes and may appear as a neck mass with spontaneous drainage. Tuberculous arthritis and osteomyelitis occur most commonly in the elderly and usually affect the lower spine and weight-bearing joints. TB of the spine is known as *Pott disease*.[2] Abnormal behavior, headaches, or convulsions suggest tuberculous meningitis. Involvement of the peritoneum, pericardium, larynx, and adrenal glands also occurs.[2,7,24]

THE ELDERLY

5 TB in the elderly is easily confused with other respiratory diseases. Many clinical findings are muted or absent altogether. Compared with younger patients, TB in the elderly is far less likely to present with positive skin tests, fevers, night sweats, sputum production, or hemoptysis.[2,24,35,36] Weight loss may occur but is nonspecific. In contrast, mental status changes are twice as common in the elderly, and mortality is six times higher.[2,24,35] TB is a preventable cause of death in the elderly that should not be overlooked.

CHILDREN

5 TB in children, especially those younger than 12 years of age, may present as a typical bacterial pneumonia and is called *progressive primary TB*.[24–26] Clinical disease often begins 1 to 2 months after exposure and precedes skin-test positivity. Unlike adults, pulmonary TB in children often involves the lower and middle lobes.[24–26] Dissemination to the lymph nodes, gastrointestinal and genitourinary tracts, bone marrow, and meninges is common. Because of delays in recruitment of cellular immunity, cavitary disease is infrequent, and the number of organisms present typically is smaller than in an adult. Because cavitary lesions are uncommon, children do not spread TB readily. However, TB can be rapidly fatal in a child, and it requires prompt chemotherapy.

DIAGNOSIS

DIAGNOSTIC TESTING

The key to stopping the spread of TB is early identification of infected individuals.[1,2,7,24] Table 121–1 lists the populations most likely to benefit from testing (column 1 patients are at highest risk for TB, followed by those in column 2). Members of these high-risk groups should be tested for TB infection and educated about the disease.

The Mantoux test is a TB skin test. It uses tuberculin purified protein derivative (PPD), and unlike the Heaf or tine test, the Mantoux test is quantitative. The standard 5-tuberculin-unit PPD dose is placed intracutaneously on the volar aspect of the forearm with a 26- or 27-gauge needle.[2,24,31] This injection should produce a small, raised, blanched wheal. An experienced professional should read

TABLE 121-1 Criteria for Tuberculin Positivity by Risk Group

Reaction 5 mm of Induration	Reaction ≥10 mm of Induration	Reaction ≥15 mm of Induration
Human immunodeficiency virus (HIV)-positive persons	Recent immigrants (i.e., within the last 5 years) from high-prevalence countries	Persons with no risk factors for TB
Recent contacts of tuberculosis (TB) case patients	Injection-drug users	
Fibrotic changes on chest radiograph consistent with prior TB	Residents and employees[a] of the following high-risk congregate settings: prisons and jails; nursing homes and other long-term care facilities for the elderly; hospitals and other healthcare facilities; residential facilities for patients with acquired immunodeficiency syndrome (AIDS); homeless shelters	
Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of ≥15 mg/day of prednisone for 1 month or more)[b]	Mycobacteriology laboratory personnel	
	Persons with the following clinical conditions that place them at high risk: silicosis; diabetes mellitus; chronic renal failure; some hematologic disorders (e.g., leukemias and lymphomas); other specific malignancies (e.g., carcinoma of the head or neck and lung); weight loss of ≥10% of ideal body weight; gastrectomy; jejunoileal bypass	
	Children younger than 4 years of age or infants, children, and adolescents exposed to adults at high risk	

[a]For persons who are otherwise at low risk and who are tested at the start of employment, a reaction of ≥15 mm induration is considered positive.
[b]Risk of TB for patients treated with corticosteroids increases with higher dose and longer duration.
Adapted from Centers for Disease Control and Prevention. Screening for tuberculosis and tuberculosis infection in high-risk populations: Recommendations of the Advisory Council for the Elimination of Tuberculosis. MMWR 1995;44(RR-11):19–34.

the test in 48 to 72 hours. The area of induration (the "bump") is the important end point, not the area of redness. Table 121–1 lists the criteria for interpretation.[1,2,7,24,31] The CDC does not recommend the routine use of anergy panels.[31,37] Aplisol and Tubersol 5-tuberculin-unit products are available commercially, but because of more predictable results, Tubersol appears to be the preferred product.

The "booster effect" occurs for patients who do not respond to an initial skin test but show a positive reaction if retested about a week later.[24,37] Patients with past *M. tuberculosis* infection and some patients with past immunization with bacillus Calmetté-Guerin (BCG) vaccine or past infection with other mycobacteria may "boost" with a second skin test. Individuals who require periodic skin testing, such as healthcare workers, should receive a two-stage test initially.[24,37,38] Once they are shown to be skin-test negative, any positive skin test later shows recent infection, and this requires treatment.

The PPD skin test is an imperfect diagnostic tool. Up to 20% of patients with active TB are falsely skin-test negative, presumably because their immune systems are overwhelmed.[21,37] False-positive results are more common in low-risk patients and those recently vaccinated with BCG. Despite BCG vaccination, one should not ignore a positive PPD result. These patients require careful evaluation for active disease, and they may be offered preventive treatment because many come from areas where TB infection is common.

Interferon gamma release assays (IGRA) measure the release of INF-γ in blood in response to the TB antigens.[39] They may provide quick and specific results for identifying *M. tuberculosis*. IGRAs do not trigger a booster effect and are more specific for testing M. tuberculosis than the PPD. The QuantiFERON-TB Gold test (QFT-G) is an enzyme-linked immunosorbent assay (ELISA) and was approved by the U.S. Food and Drug Administration in 2005.[40] The T-SPOT.TB, an enzyme linked immunospot (ELISPOT) assay, was approved by the U.S. Food and Drug Administration in 2008.[41] Both tests can be used for diagnosing latent tuberculosis infection and tuberculosis disease caused by *M. tuberculosis*. The antigenic proteins are absent from BCG vaccine strains and from most nontuberculosis mycobacteria. Therefore, QFT-G does not trigger a booster effect and is more specific for testing of *M. tuberculosis* than the PPD. Although these tests can provide results to diagnose both latent infection and disease, they can not differentiate between the two. Results are available within <24 hours, instead of the 2 to 3 days required for the traditional PPD skin test. Therefore, the patient does not have to return to the clinic as required by the PPD skin test, making it more convenient. The CDC recognizes the use of these tests in all circumstances in which the PPD is currently used; however, the sensitivity for young children, immunocompromised patients has not been determined.[42–45]

ADDITIONAL TESTS

When active TB is suspected, attempts should be made to isolate *M. tuberculosis* from the site of infection.[2,7,24,37] Sputum collected in the morning usually has the highest yield.[2,12,24] Daily sputum collection over 3 consecutive days is recommended.

For patients unable to expectorate, sputum induction with aerosolized hypertonic saline may produce a diagnostic sample. Bronchoscopy, or aspiration of gastric fluid via a nasogastric tube, may be attempted for select patients.[24] For patients with suspected extrapulmonary TB, samples of draining fluid, biopsies of the infected site, or both may be attempted. Blood cultures are positive occasionally, especially in AIDS patients.[24,34,46]

TREATMENT

Tuberculosis

DESIRED OUTCOMES

The desired outcomes for the treatment of tuberculosis are

1. Rapid identification of a new TB case
2. Initiation of specific antituberculosis treatment
3. Prompt resolution of the signs and symptoms of disease
4. Achievement of a noninfectious state in the patient, thus ending isolation
5. Adherence to the treatment regimen by the patient
6. Cure of the patient as quickly as possible (generally at least 6 months of treatment)

It is also important that patients with active disease are isolated to prevent spread of the disease and that appropriate samples for smears and cultures are collected. Secondary goals are identification of the index case that infected the patient, identification of all persons infected by both the index case and the new case of TB ("contact investigation"), and completion of appropriate treatments for those individuals.

GENERAL APPROACHES TO TREATMENT

Drug treatment is the cornerstone of TB management.[2,7,14,47] Monotherapy can be used only for infected patients who do not have active TB (latent infection, as shown by a positive skin test). Once active disease is present, a minimum of two drugs, and generally three or four drugs, must be used simultaneously.[2,7,14,47] The duration of treatment depends on the condition of the host, extent of disease, presence of drug resistance, and tolerance of medications. The shortest duration of treatment generally is 6 months, and 2 to 3 years of treatment may be necessary for cases of multidrug-resistant TB (MDR-TB).[2,7,14,47] Because the duration of treatment is so long and because many patients feel better after a few weeks of treatment, careful follow-up is required. Directly observed therapy by a healthcare worker is a cost-effective way to ensure completion of treatment.[2,7,14,47–49]

PRINCIPLES FOR TREATING LATENT INFECTION AND FOR TREATING DISEASE

Asymptomatic patients with tuberculous infection have a bacillary load of about 10^3 organisms, compared with 10^{11} organisms in a patient with cavitary pulmonary TB.[2,7,50] As the number of organisms increases, the likelihood of naturally occurring drug-resistant mutants also increases. Naturally occurring resistant mutants are found at rates of 1 in 10^6 to 1 in 10^8 organisms for the antituberculosis drugs.[2,47,50] When treating asymptomatic latent infection with isoniazid monotherapy, the risk of selecting out isoniazid-resistant organisms is low. The isoniazid mutation rate is about 1 in 10^6, but only about 10^3 organisms are present in the body. In contrast, the risk of selecting out isoniazid-resistant organisms is unacceptably high for patients with cavitary TB. One can prevent selection of these resistant mutants by adding more drugs because the rates for resistance mutations to multiple drugs are additive functions of the individual rates. For example, only 1 in 10^{13} organisms would be naturally resistant to both isoniazid (1 in 10^6) and rifampin (1 in 10^7).[2,47,50] It is unlikely that such rare organisms are present in a previously untreated patient.

Combination chemotherapy is required for treating active TB disease. The patient should receive at least two drugs to which the isolate is susceptible, and generally, four drugs are given at the outset of treatment. Rifampin and isoniazid are the best drugs for preventing drug resistance, followed by ethambutol, streptomycin, and pyrazinamide.[2,7,47,50,51]

Three subpopulations of mycobacteria are proposed to exist within the body, and each appears to respond to certain drugs.[2,47,50] Most numerous are the extracellular, rapidly dividing bacteria, often found within cavities (about 10^7 to 10^9 organisms). These are killed most readily by isoniazid, followed by rifampin, streptomycin, and the other drugs. A second group resides within caseating granulomas (possibly 10^5 to 10^7 organisms). These organisms appear to be in a semidormant state, with occasional bursts of metabolic activity. Pyrazinamide, through its conversion within *M. tuberculosis* to pyrazinoic acid, appears most active against these organisms. Rifampin and isoniazid also may be active against this subpopulation. The third subset is the intracellular mycobacteria present within macrophages (10^4 to 10^6). Rifampin, isoniazid, and the quinolones appear to be most active against intracellular *M. tuberculosis*. While this appears to explain what happens during the treatment of TB, there is no practical way to quantitate these populations within a given patient.

NONPHARMACOLOGIC THERAPY

7 Nonpharmacologic interventions aim to (a) prevent the spread of TB, (b) find where TB has already spread using contact investigation, and (c) replenish the weakened (consumptive) patient to a state of normal weight and well-being. The first two items are performed by public health departments. Clinicians involved in the treatment of TB should verify that the local health department has been notified of all new cases of TB.

Workers in hospitals and other institutions must prevent the spread of TB within their facilities.[2,4,14,31] All such workers should learn and follow each institution's infection control guidelines. This includes using personal protective equipment, including properly fitted respirators, and closing doors to "negative pressure" rooms. These hospital isolation rooms draw air in from surrounding areas rather than blowing air (and *M. tuberculosis*) into these surrounding areas. The air from the isolation room may be treated with ultraviolet lights and then vented safely outside. However, these isolation rooms work properly only if the door is closed.

Debilitated TB patients may require therapy for other medical problems, including substance abuse and HIV infection, and some may need nutritional support. Therefore, clinicians involved in substance abuse rehabilitation and nutritional support services should be familiar with the needs of TB patients.

Surgery may be needed to remove destroyed lung tissue, space-occupying infected lesions (*tuberculomas*), and certain extrapulmonary lesions.[2,14,47] Vaccines against TB include BCG and *M. vaccae*.[47] However, these vaccines are of limited value, and neither can prevent infection by *M. tuberculosis*. BCG (discussed below) may prevent extreme forms of TB in infants, whereas *Mycobacterium vaccae* can not be recommended.[47,52]

PHARMACOLOGIC THERAPY

Treating Latent Infection

Isoniazid is the preferred drug for treating latent TB infection.[2,7,14,47] Generally, isoniazid alone is given for 9 months. The treatment of latent TB infection (LTBI) reduces a person's lifetime risk of active TB from approximately 10% to approximately 1%. Because TB is spread easily through the air, each case prevented also prevents a second wave of cases that each prevented case would have produced. Historically, the treatment of LTBI has been called *prophylaxis, chemoprophylaxis,* or *preventive treatment.* By any name, it is one of the primary mechanisms for reducing TB in the United States. Table 121–2 lists the LTBI treatment options.

Because young children, the elderly, and HIV-positive patients are at greater risk of active disease once infected with *M. tuberculosis*, they require careful evaluation. Once active TB is ruled out, they should receive treatment for latent infection.[2,23,24,47]

The keys to successful treatment of LTBI are (a) infection by an isoniazid-susceptible isolate, (b) adherence to the 9-month regimen, and (c) no exogenous reinfection.[2] Isoniazid adult doses are usually 300 mg daily (5 to 10 mg/kg of body weight)[47] (see Table 121–2). Lower doses are less effective.[2,53,54] Isoniazid should be given on an empty stomach, and antacids should be avoided within 2 hours of dosing. When adherence is an issue, twice-weekly isoniazid (900 mg in an adult) can be given using directly observed treatment. Nine months of treatment is recommended, but 6 months still provides considerable benefit.

Rifampin 600 mg daily for 4 months can be used when isoniazid resistance is suspected or when the patient cannot tolerate isoniazid.[2,26,47] Rifabutin 300 mg daily might be substituted for rifampin for patients at high risk of drug interactions. The combination of pyrazinamide plus rifampin is no longer recommended because of higher than expected rates of hepatotoxicity. When resistance to isoniazid and rifampin is suspected in the isolate causing infection, there is no regimen proved to be effective.[2,47] Regimens that *might* be effective include ethambutol plus levofloxacin, but data regarding efficacy are lacking.

TABLE 121-2 Recommended Drug Regimens for Treatment of Latent Tuberculosis (TB) Infection in Adults

Drug	Interval and Duration	Comments	Rating[a] (Evidence)[b] HIV-	HIV+
Isoniazid	Daily for 9 months[b,c]	In human immunodeficiency virus (HIV)-infected patients, isoniazid may be administered concurrently with nucleoside reverse transcriptase inhibitors (NRTIs), protease inhibitors, or nonnucleoside reverse transcriptase inhibitors (NNRTIs)	A (II)	A (II)
	Twice weekly for 9 months[b,c]	Directly observed therapy (DOT) must be used with twice-weekly dosing.	B (II)	B (II)
Isoniazid	Daily for 6 months[c]	Not indicated for HIV-infected persons, those with fibrotic lesions on chest radiographs, or children	B (I)	C (I)
	Twice weekly for 6 months[c]	DOT must be used with twice-weekly dosing	B (II)	B (III)
Rifampin	Daily for 4 months	For persons who are contacts of patients with isoniazid-resistant, rifampin-susceptible TB who can not tolerate pyrazinamide	B (II)	C (I)

[a]Strength of recommendation: A, preferred; B, acceptable alternative; C, offer when A and B can not be given.
[b]Quality of evidence: I, randomized clinical trial data; II, data from clinical trials that are not randomized or were conducted in other populations; III, expert opinion.
[c]Recommended regimen for children younger than 18 years of age.
[d]Recommended regimen for pregnant women. Some experts would use rifampin and pyrazinamide for 2 months as an alternative regimen in HIV-infected pregnant women, although pyrazinamide should be avoided during the first trimester.
Adapted from Centers for Disease Control and Prevention. Targeted tuberculin testing and treatment of latent tuberculosis infection. MMWR 2000;49(RR-6):31.

For recent skin-test converters of all ages, the risk of active TB outweighs the risk for drug toxicity.[31,47] Pregnant women, alcoholics, and patients with poor diets who are treated with isoniazid should receive pyridoxine (vitamin B6) 10 to 50 mg daily to reduce the incidence of central nervous system (CNS) effects or peripheral neuropathies. All patients who receive treatment of LTBI should be monitored monthly for adverse drug reactions and for possible progression to active TB.

Treating Active Disease

8 The treatment of active TB requires the use of multiple drugs. There are two primary antituberculosis drugs, isoniazid and rifampin, with the rest of the drugs having specific roles.[47,50,51] Isoniazid and rifampin should be used together whenever possible. Typically, *M. tuberculosis* is either very susceptible or very resistant to a given drug. This contrasts with *M. avium*, where moderately resistant organisms are a frequent occurrence. Theoretically, MIC results could be used to guide dosing in the treatment of moderately resistant *M. tuberculosis*, but this remains to be studied prospectively.[2,14,47]

Drug-susceptibility testing should be done on the initial isolate for all patients with active TB. These data should guide the selection of drugs over the course of treatment.[2,7,14,47] However, some patients are unable to provide a suitable specimen for laboratory testing. If susceptibility data are not available for a given patient, the drug-susceptibility data for the suspected source case or regional susceptibility data should be used.[2,47]

Drug resistance should be expected for patients presenting for the retreatment of TB. These patients require retesting of drug susceptibility using freshly collected specimens. It is imperative to learn what drugs the patient received and for how long the patient received them.[2,14,47] A treatment history, often called a *drug-o-gram*, shows the start and stop dates of all antimycobacterial drugs on a horizontal bar graph.[2,47] A drug-o-gram should be constructed for all retreatment patients.

10 The standard TB treatment regimen is isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin for 4 months, a total of 6 months of treatment.[2,14,47] If susceptibility to isoniazid, rifampin, and pyrazinamide is shown, ethambutol can be stopped at any time. Without pyrazinamide, a total of 9 months of isoniazid and rifampin treatment is required. Table 121–3 shows the recommended treatment regimens. When intermittent therapy is used, directly observed treatment is essential. Doses missed during an intermittent TB regimen decrease its efficacy and increase the relapse rate. Note that Table 121–3 shows recommendations that differ for HIV-negative and HIV-positive patients. HIV-positive patients should not receive highly intermittent regimens. In general, regimens given daily five times each week or three times weekly can be used for HIV-positive patients. Less-frequent dosing is associated with higher failure and relapse rates and the selection of rifampin-resistant organisms.[47]

When a patient's sputum smears convert to a negative, the risk of the patient infecting others is greatly reduced, but it is not zero.[2,22,47] Such patients can be removed from respiratory isolation, but they must be careful not to cough on others and should meet with others only in well-ventilated places. Smear-negative patients still may be culture positive, so they still can transmit TB to others.

Patients who are slow to respond clinically, those who remain culture positive at 2 months of treatment, those with cavitary lesions on chest radiograph, and perhaps HIV-positive patients should be treated for a total of 9 months and for at least 6 months from the time that they convert to smear and culture negativity.[2,7,14,47] Some authors recommend therapeutic drug monitoring for such patients.[2,47,51,53] When isoniazid and rifampin can not be used, treatment durations become 2 years or more regardless of immune status.[2,14,47,51]

Adjustments to the regimen should be made once the susceptibility data are available.[2,14,47] If the organism is drug-resistant, careful consideration of the remaining therapeutic options must be made. Two or more drugs with in vitro activity against the patient's isolate and that the patient has not received previously should be added to the regimen, as needed.[2,14,47] TB specialists should be consulted regarding cases of drug-resistant TB.[2,14,47]

9 There is no standard regimen for MDR-TB.[2,14,47] Each patient's exposure history, previous treatment history (including toxicity and adherence issues), and current susceptibility data must be considered simultaneously. *It is critical to avoid monotherapy, and it is critical to avoid adding a single drug to a failing regimen.*[2,14,47] Adding one drug at a time leads to the sequential selection of drug resistance until there are no drugs left. The treatment of MDR-TB should be managed by TB specialists. It may take several months for a patient with MDR-TB to become culture negative because the drugs used lack the potency of isoniazid and rifampin.[2,50,51] Consequently, prolonged respiratory isolation may be required.

Drug resistance should be suspected in the following situations:

- Patients who have received prior therapy for TB
- Patients from areas with a high prevalence of resistance (South Africa, Mexico, Southeast Asia, the Baltic countries, and the former Soviet states)
- Patients who are homeless, institutionalized, intravenous drug abusers, or infected with HIV

TABLE 121-3 Drug Regimens for Culture-Positive Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

Initial phase			Continuation Phase				Rating[a] (Evidence)[b]	
Regimen	***Drugs***	***Interval and Doses[c] (Minimal Duration)***	***Regimen***	***Drugs***	***Interval and Doses[c,d] (Minimal Duration)***	***Range of Total Doses (Minimal Duration)***	***HIV-***	***HIV+***
1	Isoniazid, rifampin, pyrazinamide, ethambutol	Seven days per week for 56 doses (8 weeks) or 5 days/week for 40 doses (8 weeks)[e]	1a	Isoniazid/ rifampin	Seven days per week for 126 doses (18 weeks) or 5 days/week for 90 doses (18 weeks)[e]	182–130 (26 weeks)	A (I)	A (II)
			1b	Isoniazid/ rifampin	Twice weekly for 36 doses (18 weeks)	92–76 (26 weeks)	A (I)	A (II)[f]
			1c[g]	Isoniazid/ rifapentine	Once weekly for 18 doses (18 weeks)	74–58 (26 weeks)	B (I)	E (I)
2	Isoniazid, rifampin, pyrazinamide, ethambutol	Seven days per week for 14 doses (2 weeks), then twice weekly for 12 doses (6 weeks) or 5 days/week for 10 doses (2 weeks)| then twice weekly for 12 doses (6 weeks)	2a	Isoniazid/ rifampin	Twice weekly for 36 doses (18 weeks)	62–58 (26 weeks)	A (II)	B (II)[f]
			2b[g]	Isoniazid/ rifapentine	Once weekly for 18 doses (18 weeks)	44–40 (26 weeks)	B (I)	E (I)
3	Isoniazid, rifampin, pyrazinamide, ethambutol	Three times weekly for 24 doses (8 weeks)	3a	Isoniazid/ rifampin	Three times weekly for 54 doses (18 weeks)	78 (26 weeks)	B (I)	B (II)
4	Isoniazid, rifampin, ethambutol	Seven days per week for 56 doses (8 weeks) or 5 days/week for 40 doses (8 weeks)[e]	4a	Isoniazid/ rifampin	Seven days per week for 217 doses (31 weeks) or 5 days/week for 155 doses (31 weeks)|	273–195 (39 weeks)	C (I)	C (II)
			4b	Isoniazid/ rifampin	Twice weekly for 62 doses (31 weeks)	118–102 (39 weeks)	C (I)	C (II)

[a]Ratings: A, preferred; B, acceptable alternative; C, offer when A and B can not be given; E, should never be given.
[b]Evidence ratings: I, randomized clinical trial; II, data from clinical trials that were not randomized or were conducted in other populations; III, expert opinion.
[c]When directly observed therapy is used, drugs may be given 5 days per week, and the necessary number of doses adjusted accordingly. Although there are no studies that compare five with seven daily doses, extensive experience indicates this would be an effective practice.
[d]Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month [31-week; either 217 doses (daily) or 62 doses (twice weekly)] continuation phase.
[e]Five-day-a-week administration is always given by directly observed therapy. Rating for 5-day-per-week regimens is A (III).
[f]Not recommended for HIV-infected patients with CD4+ cell counts <100 cells/μL.
[g]Options 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph (see text). For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.
From Centers for Disease Control and Prevention. Treatment of tuberculosis. MMWR 2003;52 (RR-11).

- Patients who still have acid-fast bacilli-positive sputum smears after 1 to 2 months of therapy
- Patients who still have positive cultures after 2 to 4 months of therapy
- Patients who fail treatment or relapse after treatment
- Patients known to be exposed to MDR-TB cases

The patients just listed should be considered infected with drug-resistant TB until proved otherwise. Empirical therapy with four or more drugs may be needed for acutely ill patients.[2,14,47] These regimens may be altered when the susceptibility pattern becomes known. If the index case is known, then the same effective regimen should be employed for the new case. Again, MDR-TB cases should be referred to specialists. A new term in use, *XDR-TB*, refers to "extensively drug-resistant TB." Such organisms are resistant to at least isoniazid, rifampin, a fluoroquinolone and one second-line injectable drug (amikacin, capreomycin, or kanamycin).[55]

Special Populations

Tuberculous Meningitis and Extrapulmonary Disease

Patients with CNS tuberculosis usually are treated for longer periods (9 to 12 months instead of 6 months) (Table 121–4).[2,14,47] In general, isoniazid, pyrazinamide, ethionamide, and cycloserine penetrate the cerebrospinal fluid readily, but rifampin, ethambutol, and streptomycin have variable CNS penetration.[54] Of the quinolones, levofloxacin may be preferred based on current data. Extrapulmonary TB of the soft tissues can be treated with conventional regimens.[2,14,47] TB of the bone typically is treated for 9 months, occasionally with surgical debridement.[2,14,47]

Children TB in children may be treated with regimens similar to those used in adults, although some physicians still prefer to extend treatment to 9 months.[2,14,24,25,47,56,57] Pediatric doses of isoniazid and rifampin on a milligram-per-kilogram basis are higher than those used in adults (Table 121–5).[47]

Pregnancy Women with TB should be cautioned against becoming pregnant because the disease poses a risk to the fetus and to the mother. If already pregnant, the usual treatment is isoniazid, rifampin, and ethambutol for 9 months.[47] Isoniazid or ethambutol are relatively safe for use in pregnant women.[2,47,54,56,57] B vitamins are particularly important during pregnancy and should be provided to women being treated for TB. Rifampin is associated rarely with birth defects, including limb reduction and CNS lesions.[54] In general, rifampin is used in pregnant women with TB. Pyrazinamide has not been studied in large numbers

TABLE 121-4 Evidence-Based[a] Guidelines for the Treatment of Extrapulmonary Tuberculosis and Adjunctive Use of Corticosteriods[b]

Site	Length of Therapy (month)	Rating (Duration)	Corticosteroids[c]	Rating (Corticosteroids)
Lymph node	6	A (I)	Not recommended	D (III)
Bone and joint	6–9	A (I)	Not recommended	D (III)
Pleural disease	6	A (II)	Not recommended	D (I)
Pericarditis	6	A (II)	Strongly recommended	A (I)
CNS tuberculosis including meningitis	9–12	B (II)	Strongly recommended	A (I)
Disseminated disease	6	A (II)	Not recommended	D (III)
Genitourinary	6	A (II)	Not recommended	D (III)
Peritoneal	6	A (II)	Not recommended	D (III)

[a]For rating system, see Table 121–3.
[b]Duration of therapy for extrapulmonary tuberculosis caused by drug-resistant organisms is not known.
[c]Corticosteroid preparations vary among studies.

of pregnant women, but anecdotal data suggest that it may be safe.[47]

Streptomycin use during pregnancy may lead to hearing loss in the newborn, including complete deafness. Streptomycin and the other aminoglycosides must be reserved for critical situations where alternatives do not exist.[2,47] Although the polypeptide capreomycin has not been studied, it probably carries the same risks.

Ethionamide may cause premature delivery and congenital deformities when used during pregnancy.[47,54] Mongolism also has been reported with ethionamide, so it cannot be recommended in this setting. *p*-Aminosalicylic acid has been used safely in pregnancy, but specific data are lacking.[47,54] Cycloserine is known to cross the placenta, but the effects on the developing fetus are not known. Therefore, cycloserine generally cannot be recommended during pregnancy.[54]

Ciprofloxacin, levofloxacin, moxifloxacin, and the other quinolones are associated with permanent damage to cartilage in the weight-bearing joints of immature animals, especially dogs and rabbits.[47,54] Although these drugs do not frequently cause joint problems in humans, other antituberculosis agents should be used during pregnancy.

Pregnant women with LTBI are not at the same level of risk compared with those with active disease. Therapy with isoniazid for LTBI may be delayed until after pregnancy or, if recent skin-test conversion has occurred, started during the second trimester of pregnancy.[47,54–57] Although most antituberculosis drugs are excreted in breast milk, the amount of drug received by the infant through nursing is insufficient to cause toxicity. Quinolones should be avoided in nursing mothers, if possible.

HIV Infection Patients with AIDS and other immunocompromised hosts may be managed with chemotherapeutic regimens similar to those used in immunocompetent individuals, although treatment is often extended to 9 months (see Table 121–3).[2,14,47] The precise duration to recommend remains a matter of debate. Highly intermittent regimens (twice or once weekly) are not recommended for HIV-positive TB patients. Prognosis has been particularly poor for HIV-infected patients infected with MDR-TB, so all efforts should be made to reduce the time between clinical presentation, diagnosis of TB, and start of appropriate treatment. Recommendations for management of HIV and TB published by the World Health Organization and others have provided guidance on monitoring of treatment, side effects, and drug interactions of HIV and TB. MDR, XDR-TB. [8,58] Differentiation must be made between infection with *M. tuberculosis* and nontuberculous mycobacteria, such as MAC, because the drugs used are different. While awaiting laboratory results, the patient can be treated empirically for TB if there is any doubt about the causative organism. Some patients with AIDS malabsorb their oral medications; this is discussed under Therapeutic Drug Monitoring below.[2,47,51,53] The major issue of drug interactions is discussed further below under Rifampin.

CLINICAL CONTROVERSY

The recommended duration of treatment often is the same for HIV-negative and HIV-positive patients. However, some clinicians believe that therapy should be extended for patients with weakened immune systems. These clinicians treat HIV-positive patients with drug-susceptible TB for 9 months rather than the usual 6 months.

Renal Failure For nearly all patients, isoniazid and rifampin do not require dose modification in renal failure. They are eliminated primarily by the liver.[51,54,59] In the unlikely event that peripheral neuropathies develop, the frequency of isoniazid dosing may be reduced. Pyrazinamide and ethambutol typically require a reduction in dosing frequency from daily to three times weekly (Table 121–6).[47,59]

Renally cleared TB drugs include the aminoglycosides (amikacin, kanamycin, and streptomycin), capreomycin, ethambutol, cycloserine, and levofloxacin.[47,54,50,60] Dosing intervals need to be extended for these drugs (see Table 121–6). Ciprofloxacin and moxifloxacin are approximately 50% cleared by the kidneys but may not require a change in dose from once daily, as used for TB. The metabolites of isoniazid, pyrazinamide, and *p*-aminosalicylic acid are cleared primarily by the kidneys. The role of these metabolites in causing toxicity is unknown, so their accumulation in renal failure may carry some risk.

Ethionamide and its sulfoxide metabolite are hepatically cleared, so dosing is unchanged.[47,60] *p*-Aminosalicylic acid is converted largely to metabolites prior to renal elimination; these metabolites may accumulate in renal failure.[60] For patients on hemodialysis, the usual 12-hour dosing interval for *p*-aminosalicylic acid granules seems to be safe. Dialysis will remove the metabolites. Serum concentration monitoring must be performed for cycloserine to avoid dose-related toxicities in renal failure patients.[51,53,60]

Hepatic Failure Antituberculosis drugs that rely on hepatic clearance for most of their elimination include isoniazid, rifampin, pyrazinamide, ethionamide, and *p*-aminosalicylic acid.[54] Ciprofloxacin and moxifloxacin are approximately 50% cleared by the liver. Elevations of serum transaminase concentrations generally are not correlated with the residual capacity of the liver to metabolize drugs, so these markers cannot be used as guides for drug dosing. Furthermore, isoniazid, rifampin, pyrazinamide, and, to a lesser degree, ethionamide,

TABLE 121-5 Doses[a] of Antituberculosis Drugs for Adults and Children[b]

Drug	Preparation	Adults/Children	Doses			
			Daily	1 × per week	2 × per week	3 × per week
First-line drugs						
Isoniazid	Tablets (50 mg, 100 mg, 300 mg); elixir (50 mg/5 mL); aqueous solution (100 mg/mL) for intravenous or intramuscular injection	Adults (max)	5 mg/kg (300 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)
		Children (max)	10–15 mg/kg (300 mg)	–	20–30 mg/kg (300 mg)	–
Rifampin	Capsule (150 mg, 300 mg); powder may be suspended for oral administration; aqueous solution for intravenous injection	Adults[c] (max)	10 mg/kg (600 mg)	–	10 mg/kg (600 mg)	10 mg/kg (600 mg)
		Children (max)	10–20 mg/kg (600 mg)	–	10–20 mg/kg (600 mg)	–

TABLE 121-5 Doses[a] of Antituberculosis Drugs for Adults and Children[b] (continued)

			Doses			
Drug	**Preparation**	**Adults/Children**	**Daily**	**1× per week**	**2× per week**	**3×per week**
Moxifloxacin[h]	Tablets (400 mg); aqueous solution (400 mg/250 mL) for intravenous injection	Adults	400 mg daily	There are no data to support intermittent administration	There are no data to support intermittent administration	There are no data to support intermittent administration

[a]Dose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.
[b]For purposes of this document, adult dosing begins at age 15 years.
[c]Dose may need to be adjusted when there is concomitant use of protease inhibitors or nonnucleoside reverse transcriptase inhibitors.
[d]The drug can likely be used safely in older children but should be used with caution in children less than 5 years of age, in whom visual acuity can not be monitored. In younger children, ethambutol at the dose of 15 mg/kg per day can be used if there is suspected or proven resistance to isoniazid or rifampin.
[e]It should be noted that although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimal dose for a given patient.
[f]The single daily dose can be given at bedtime or with the main meal.
[g]Dose: 15 mg/kg per day (1 g) but 10 mg/kg in persons older than 59 years of age (750 mg). Usual dose: 750–1,000 mg administered intramuscularly or intravenously, given as a single dose 5–7 days/week and reduced to two or three times per week after the first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.
[h]The long-term (more than several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.

p-aminosalicylic acid, and, rarely, ethambutol may cause hepatotoxicity.[47,51,54] For some patients with drug-susceptible TB, a "liver-sparing" regimen of streptomycin, levofloxacin, and ethambutol may be used, at least temporarily.[47,51,54] Because this regimen requires 18 or more months of treatment to be successful, patients usually are switched to isoniazid- and rifampin-containing regimens as soon as they are able.

TABLE 121-6 Dosing Recommendations for Adult Patients with Reduced Renal Function and for Adult Patients Receiving Hemodialysis

Drug	**Change in Frequency?**	**Recommended Dose and Frequency for Patients with Creatinine Clearance <30 mL/min or for Patients Receiving Hemodialysis**
Isoniazid	No change	300 mg once daily or 900 mg three times per week
Rifampin	No change	600 mg once daily or 600 mg three times per week
Pyrazinamide	Yes	25–35 mg/kg per dose three times per week (not daily)
Ethambutol	Yes	15–25 mg/kg per dose three times per week (not daily)
Levofloxacin	Yes	750–1,000 mg per dose three times per week (not daily)
Cycloserine	Yes	250 mg once daily or 500 mg/dose three times per week[a]
Ethionamide	No change	250–500 mg/dose daily
p-Aminosalicylic acid	No change	4 g/dose, twice daily
Streptomycin	Yes	12–15 mg/kg per dose two or three times per week (not daily)
Capreomycin	Yes	12–15 mg/kg per dose two or three times per week (not daily)
Kanamycin	Yes	12–15 mg/kg per dose two or three times per week (not daily)
Amikacin	Yes	12–15 mg/kg per dose two or three times per week (not daily)

Standard doses are given unless there is intolerance.
The medications should be given after hemodialysis on the day of hemodialysis.
Monitoring of serum drug concentrations should be considered to ensure adequate drug absorption, without excessive accumulation, and to assist in avoiding toxicity.
Data currently are not available for patients receiving peritoneal dialysis. Until data become available, begin with doses recommended for patients receiving hemodialysis, and verify adequacy of dosing, using serum concentration monitoring.
[a]The appropriateness of 250 mg daily doses has not been established. There should be careful monitoring for evidence of neurotoxicity.

Morbid Obesity Data are not available for dosing the TB drugs for patients with morbid obesity.[54] Relatively hydrophilic drugs (isoniazid, pyrazinamide, the aminoglycosides, capreomycin, ethambutol, *p*-aminosalicylic acid, and cycloserine) can be dosed initially based on ideal body weight. Very low or very high serum concentrations can be avoided by checking the serum concentrations.

The TB Drugs

The interested reader is referred to several other publications for more detailed information regarding these drugs.[2,13,47,50,51,53,54,61–63] Note that although the American Thoracic Society (ATS)/CDC guidelines recommend "maximum" doses. (see Table 121–5).[47] In the author's view, the "maximum" dose for a given patient is the dose that produces the desired response with an acceptable level of toxicity.[51,53] This can only be determined on a case-by-case basis. Artificially capping doses may deprive patients of needed drug.

Primary Antituberculosis Drugs *Isoniazid* Isoniazid is one of the two most important TB drugs. It is highly specific for mycobacteria, with a MIC against *M. tuberculosis* of 0.01 to 0.25 mcg/mL. Most nontuberculous mycobacteria such as *M. avium* are resistant to isoniazid, although *M. kansasii* and *Mycobacterium xenopi* are susceptible. The most common mechanisms of resistance result from mutations in the *katG* or *inhA* genes.

Isoniazid is readily absorbed from the gastrointestinal tract and from intramuscular injection sites. It also can be given as a short intravenous infusion over 5 minutes if diluted in about 20 mL of normal saline.[64] Isoniazid should be given on an empty stomach whenever possible.[65] *N*-Acetyltransferase 2 forms the principal metabolite acetylisoniazid, which lacks antimycobacterial activity. The rate at which humans acetylate isoniazid is determined genetically; slow acetylation is an autosomal recessive trait and reflects a relative lack of *N*-acetyltransferase 2. Fast acetylators have isoniazid half-lives of less than 2 hours. Approximately 50% of whites and blacks and 80% to 90% of Asians and Eskimos are rapid acetylators. Slow acetylators have isoniazid half-lives of 3 to 4 hours and may be at an increased risk of neurotoxicity. The association of acetylator status and risk of hepatotoxicity, however, appears to be weak.[66] Poor absorption and rapid clearance of isoniazid for patients receiving highly intermittent therapy are associated with poor clinical outcomes.[67,68]

Transient elevations of the serum transaminases occur in 12% to 15% of patients receiving isoniazid and usually occur within

the first 8 to 12 weeks of therapy.[47] Overt hepatotoxicity, however, occurs in only 1% of cases. Risk factors for hepatotoxicity include patient age, preexisting liver disease, excessive alcohol intake, pregnancy, and the postpartum state. Isoniazid also may result in neurotoxicity, most frequently presenting as peripheral neuropathy or, in overdose, as seizures and coma. Patients with pyridoxine deficiency, such as pregnant women, alcoholics, children, and the malnourished, are at increased risk. Isoniazid may inhibit the metabolism of phenytoin, carbamazepine, primidone, and warfarin.[51] Patients who are being treated with these agents should be monitored closely, and appropriate dose adjustments should be made when necessary.

Rifampin The introduction of rifampin into routine use during the 1970s allowed for true short-course treatment of TB (6 to 9 months).[2,14,47] Without rifampin, treatment is generally 18 months or longer. Drug resistance to rifampin is an ominous prognostic factor because it is frequently associated with isoniazid resistance and leaves the patient with few good therapeutic options. Clinicians *must* take care to protect susceptibility to rifampin by carefully treating their patients. Rifampin shows bactericidal activity against *M. tuberculosis* and several other mycobacterial species, including *M. bovis* and *M. kansasii.*[69] Other nontuberculous mycobacteria, including MAC, show variable susceptibility to rifampin. Rifampin also is active against a broad array of other bacteria. Alteration of the target site on RNA polymerase, primarily through changes in the *rpoB* gene, leads to most forms of rifampin resistance.[47,69]

Rifampin usually is given orally, but it also can be given as a 30-minute intravenous infusion.[61,69] Oral doses are best given on an empty stomach.[70] Patients with AIDS, diabetes, and other gastrointestinal problems appear to have difficulty absorbing rifampin after oral doses, and this has been associated with therapeutic failures in some cases.[51,53,68,71] Rifampin is metabolized to 25-desacetylrifampin, which retains some of rifampin's activity; most of rifampin and its metabolite are cleared in the bile. Rifampin generally is given at 600 mg daily or intermittently, although this dose does not take full advantage of rifampin's concentration-dependent killing.[51,53] Higher doses should be tested in humans within the context of clinical trials.

Elevations in hepatic enzymes have been attributed to rifampin in 10% to 15% of patients, with overt hepatotoxicity occurring in less than1%.[47,69] More frequent adverse effects of rifampin include rash, fever, and gastrointestinal distress. Allergic reactions to rifampin have been reported and occur more frequently with intermittent rifampin doses 900 mg or more twice weekly. These reactions may take the form of a flu-like syndrome with development of fever, chills, headache, arthralgias, and, rarely, hypotension and shock.[47,62] Alternatively, hemolytic anemia or acute renal failure may occur, requiring permanent discontinuation.

Rifampin's potent induction of hepatic enzymes, especially cytochrome P450 3A4, may enhance the elimination of many other drugs, most notably the protease inhibitors used to treat HIV (Table 121–7). HIV-positive patients may benefit from the use of rifabutin instead of rifampin (see below).[47,72–75] Furthermore, women who use oral contraceptives must use another form of contraception during therapy because increased clearance of the hormones may lead to unexpected pregnancies. Patient records should be reviewed for potential drug interactions before dispensing rifampin.[61] Rifampin may turn urine and other secretions orange-red and may permanently stain some types of contact lenses.

Other Rifamycins Rifabutin is used for disseminated *M. avium* infection in AIDS patients and is quite active against *M. tuberculosis*. Most rifampin-resistant organisms are resistant to rifabutin.

CLINICAL CONTROVERSY

Rifampin shows concentration-dependent killing. Larger doses produce higher concentrations that more effectively kill bacteria and mycobacteria. High-dose rifampin fell out of favor because high doses given once or twice weekly caused flu-like symptoms. However, high doses (900 to 1,200 mg and possibly higher) can be given safely daily. Studies should be performed in humans with TB to take full advantage of rifampin's potent activity.

Because rifabutin is a less potent enzyme inducer than rifampin, it may be used for patients who are receiving protease inhibitors.[47,72–75] For HIV-positive patients, the ATS/CDC recommends regimens with three or more doses of the TB drugs per week (see Table 121–3). Rifapentine is a long-acting rifamycin that can be used once weekly in the continuation phase of treatment (after the first 2 months) in carefully selected HIV-negative patients. Rifapentine is approximately 85% as potent an enzyme inducer as rifampin, so similar drug interactions are likely.[47,72–75]

Pyrazinamide Adding pyrazinamide to the first 2 months of treatment with isoniazid and rifampin shortens the duration to 6 months for most patients.[2,47] It is usually well absorbed and displays a fairly long half-life.[76,77] The most common toxicities of pyrazinamide are gastrointestinal distress, arthralgias, and elevations in the serum uric acid concentrations.[47,62] Most patients do not experience true gout. Hepatotoxicity is the major limiting adverse effect and is dose-related when pyrazinamide is given daily.

A fixed-combination product (Rifater, Aventis) of rifampin 120 mg, isoniazid 50 mg, and pyrazinamide 300 mg is designed to prevent drug resistance by keeping the self-medicating patient from using only one drug at a time. If the patient is receiving directly observed treatment, there is no particular advantage to this product. The typical dose of Rifater will be five to six tablets daily. When pyrazinamide is discontinued after 2 months of treatment, the combination product Rifamate (isoniazid 150 mg and rifampin 300 mg) can be substituted.

Ethambutol Ethambutol replaced *p*-aminosalicylic acid as a first-line agent in the 1960s because it was better tolerated by patients.[2,47] Ethambutol is used as a fourth drug for TB while awaiting susceptibility data.[47] If the organism is susceptible to isoniazid, rifampin, and pyrazinamide, ethambutol can be stopped. Ethambutol is active against most mycobacteria, including *M. tuberculosis* and *M. avium*, but it is generally bacteriostatic.

Ethambutol should not be given with antacids.[78] For patients with renal failure, the ethambutol dose should be reduced to three times per week.[59,79] Retrobulbar neuritis is the major adverse effect. Patients may complain of a change in visual acuity, the inability to see the color green, or both. They should be monitored monthly while on the drug using Snellen wall charts for visual acuity and Ishihara red-green color discrimination cards.[47,61,62]

Second-Line Antituberculosis Drugs

Streptomycin Streptomycin is one of three aminoglycoside antibiotics (along with amikacin and kanamycin) that are active against mycobacteria. Streptomycin is quite active against MAC and several other mycobacteria, enterococci, *Brucella, Yersinia*, and various other bacteria. Although labeled only for intramuscular dosing, streptomycin can be given safely as intravenous infusions (100 mL of dextrose 5% water or normal saline) over 30 minutes, similar to the other aminoglycosides.[80] Streptomycin, like other aminoglycosides, is renally cleared by glomerular filtration and must be given less often to patients with renal dysfunction.[47,51,61]

TABLE 121-7 Clinically Significant Drug–Drug Interactions Involving the Rifamycins

Drug Class	Drugs Whose Concentrations Are Substantially Decreased by Rifamycins (References)	Comments
Antiinfectives	HIV-1 protease inhibitors	Can be used with rifabutin. Ritonavir, 400–600 mg twice daily, probably can be used with rifampin. The combination of saquinavir and ritonavir can also be used with rifampin.
	Nonnucleoside reverse transcriptase inhibitors	Delavirdine should not be used with any rifamycin. Doses of nevirapine and efavirenz need to be increased if given with rifampin; no dose increase needed if given with rifabutin.
	Macrolide antibiotics (not azithromycin)	Azithromycin has no significant interaction with rifamycins.
	Doxycycline	May require use of a drug other than doxycycline.
	Azole antifungal agents	Itraconazole, ketoconazole, and voriconazole concentrations may be subtherapeutic with any of the rifamycins. Fluconazole can be used with rifamycins, but the dose of fluconazole may have to be increased.
	Atovaquone	Consider alternate form of *Pneumocystis carinii* treatment or prophylaxis.
	Chloramphenicol	Consider an alternative antibiotic.
	Mefloquine	Consider alternate form of malaria prophylaxis.
Hormone therapy	Ethinylestradiol, norethindrone	Women of reproductive potential on oral contraceptives should be advised to add a barrier method of contraception when taking a rifamycin.
	Tamoxifen	May require alternate therapy or use of a nonrifamycin-containing regimen.
	Levothyroxine	Monitoring of serum thyroid-stimulating hormone recommended; may require increased dose of levothyroxine.
Narcotics	Methadone	Rifampin and rifapentine use may require methadone dose increase; rifabutin infrequently causes methadone withdrawal.
Anticoagulants	Warfarin	Monitor prothrombin time; may require two- to threefold dose increase.
Immunosuppressive agents	Cyclosporine, tacrolimus	Rifabutin may allow concomitant use of cyclosporine and a rifamycin; monitoring of cyclosporine serum concentrations may assist with dosing.
	Corticosteroids	Monitor clinically; may require two- to threefold increase in corticosteroid dose.
Anticonvulsants	Phenytoin, lamotrigine	Therapeutic drug monitoring recommended; may require anticonvulsant dose increase.
Cardiovascular agents	Verapamil, nifedipine, diltiazem (a similar interaction is also predicted for felodipine and nisoldipine)	Clinical monitoring recommended; may require change to an alternate cardiovascular agent.
	Propranolol, metoprolol	Clinical monitoring recommended; may require dose increase or change to an alternate cardiovascular drug.
	Enalapril, losartan	Monitor clinically; may require a dose increase or use of an alternate cardiovascular drug.
	Digoxin (among patients with renal insufficiency), digitoxin	Therapeutic drug monitoring recommended; may require digoxin or digitoxin dose increase.
	Quinidine	Therapeutic drug monitoring recommended; may require quinidine dose increase.
	Mexiletine, tocainide, propafenone	Clinical monitoring recommended; may require change to an alternate cardiovascular drug.
Bronchodilators	Theophylline	Therapeutic drug monitoring recommended; may require theophylline dose increase.
Sulfonylurea hypoglycemics	Tolbutamide, chlorpropamide, glyburide, glimepiride, repaglinide	Monitor blood glucose; may require dose increase or change to an alternate hypoglycemic drug.
Hypolipidemics	Simvastatin, fluvastatin	Monitor hypolipidemic effect; may require use of an alternate hypolipidemic drug.
Psychotropic drugs	Nortriptyline	Therapeutic drug monitoring recommended; may require dose increase or change to alternate psychotropic drug.
	Haloperidol, quetiapine	Monitor clinically; may require a dose increase or use of an alternate psychotropic drug.
	Benzodiazepines, zolpidem, buspirone	Monitor clinically; may require a dose increase or use of an alternate psychotropic drug.

Streptomycin occasionally causes nephrotoxicity, although it tends to be mild and reversible. It also is capable of causing ototoxicity (vestibular and cochlear), which may become permanent with continued use.[47,62] Older patients and those receiving long durations of treatment are most likely to experience hearing loss, whereas vestibular toxicity is highly unpredictable.

Resistance to amikacin and kanamycin is frequently linked but independent of resistance to streptomycin and independent of resistance to capreomycin. Therefore, susceptibility tests should guide the selection of these injectable drugs.

p-*Aminosalicylic Acid* In the United States, only the enteric-coated, sustained-release granule form (Paser) is available.[81–83] Gastrointestinal disturbances are the most common adverse effects from *p*-aminosalicylic acid. Diarrhea is usually self-limited, with symptoms improving after the first 1 to 2 weeks of therapy. Occasionally, a few doses of an opioid will resolve the problem. It also is important to tell the patient that the empty granules will appear in the stool. Although FDA approved for three daily doses, pharmacokinetic data support twice-daily dosing.[82]

Various types of malabsorption, including steatorrhea, were reported with previous dosage forms of *p*-aminosalicylic acid. Hypersensitivity and, rarely, severe hepatitis may occur. *p*-Aminosalicylic acid is known to produce goiter, with or without myxedema, that seems to occur more frequently with concomitant ethionamide therapy.

Cycloserine Cycloserine is only used to treat MDR-TB. It is well absorbed orally and is best taken on an empty stomach.[84] It is cleared primarily through the kidneys by glomerular filtration and requires dosage reduction in renal failure. Cycloserine can produce dose-related CNS toxicity, including lethargy, confusion, or unusual behavior. Seizures, although reported, are exceedingly rare in U.S. patients.[2,47,61] Therapy is improved by maintaining 2-hour postdose serum concentrations between 20 and 35 mcg/mL.[51,53] Most patients reach a maximum dose of 750 mg daily, divided unevenly into two doses. This can be achieved by starting with 250 mg daily for 2 days, followed by 250 mg increments over 2-day intervals. This dose of cycloserine can be maintained if the patient complains of only occasional mild CNS effects, such as difficulty concentrating. Serum concentrations can be checked 1 to 2 weeks into therapy. The

addition of pyridoxine 50 mg daily may improve patient tolerance of cycloserine.

Ethionamide Ethionamide shares structural features with two other antimycobacterial agents, isoniazid and, more distantly, thiacetazone, a drug not used in the United States. Prothionamide, the *n*-propyl derivative of ethionamide, is used in Europe. Ethionamide is only active against organisms of the genus *Mycobacterium*, and it should be considered primarily bacteriostatic because it is difficult to achieve serum concentrations that would be bactericidal.[47,51,53]

Gastrointestinal toxicity is the dose-limiting adverse effect. The drug should be introduced gradually in 250 mg increments, as described earlier for cycloserine. Rarely will a patient tolerate more than 1,000 mg daily in divided oral doses. Ethionamide may be administered with a light snack or prior to bedtime to minimize gastrointestinal intolerance. Food does not affect absorption significantly.[85] Little ethionamide is recovered in the urine, so doses remain the same in renal failure. Ethionamide may cause goiter with or without hypothyroidism (especially when given with *p*-aminosalicylic acid), gynecomastia, alopecia, impotence, menorrhagia, photodermatitis, and acne. The management of diabetes also may be more difficult for patients receiving ethionamide. Because of these problems, ethionamide only is used when necessary.

Clofazimine Clofazimine is a drug with good activity against *Mycobacterium leprae* and weak activity against *M. tuberculosis* and *M. avium*. It is used in doses of 100 mg daily in advanced cases of MDR-TB or MAC, especially when therapeutic options are limited.[47,51] The drug has a terminal elimination half-life that is weeks long. Gastrointestinal distress and skin discoloration are the most important adverse reactions. Although uncommon, severe gastrointestinal pain may occur because of deposition of clofazimine crystals within the intestines; this may require surgical correction.

Thiacetazone Thiacetazone is a weak agent used rarely in parts of the developing world because of its low cost. Skin reactions, including rash and Stevens-Johnson syndrome, may occur. Thiacetazone must be discontinued permanently as soon as a rash appears. Similar to trimethoprim-sulfamethoxazole, the incidence of skin reactions is much higher for AIDS patients.[86]

Quinolones Levofloxacin, gatifloxacin (outside of the United States), and moxifloxacin are sometimes used to treat MDR-TB because of their excellent activity against *M. tuberculosis*. Several studies have suggested a potential role for moxifloxacin as a possible replacement for certain first-line agents.[2,14,47,51,87–89] Moxifloxacin has been compared with isoniazid and ethambutol during the first 8 weeks of therapy for pulmonary TB. Moxifloxacin did not demonstrate a significant increase in 8-week culture negativity when compared to isoniazid. However, shorter time to culture conversion was seen when compared with ethambutol. Quinolones are useful because most are available in oral and intravenous dosage forms, so they can be used in critically ill patients.

β-Lactam and β-Lactamase Inhibitor Combinations The β-lactams have limited activity against mycobacteria because of β-lactamases and because β-lactams fail to enter macrophages.[47,51,90] Cefoxitin, a β-lactamase–stable cephalosporin, has useful activity against rapidly growing mycobacteria, such as *M. fortuitum* and *Mycobacterium chelonae*. Combinations of β-lactam with β-lactamase inhibitors have been used in salvage regimens for TB patients with no other options, but they are not used routinely to treat TB.

Macrolides/Azalides The macrolide clarithromycin and azalide azithromycin represent substantial advances in the treatment of MAC but demonstrate limited activity against *M. tuberculosis* and are not used frequently for TB.[2,14,47,51]

New Drugs and Delivery Systems The nitroimidazole derivatives PA824 and OPC67683, which are chemically related to metronidazole and tinidazole, have activity against *M. tuberculosis* in vitro and in animal models.[91,92] Early clinical data appear to be promising. Aerosol dry powder formulation is a promising delivery system for PA824.[93] This class, along with the oxazolidinones, may produce useful agents for TB. The diarylquinoline TMC207 has potent in vitro and in vivo activity against both TB and MDR-TB. TMC207 works through targeting the ATP synthase pump. Phase I studies in humans have shown the drug to be well tolerated.[94] Linezolid has been used in some patients with MDR-TB.[95] Long-term use of linezolid requires careful monitoring of hematologic indices for potential anemia and thrombocytopenia. It may be possible to reduce the incidences of these toxicities by giving linezolid 600 mg daily or 300 mg twice daily for the slow-growing *M. tuberculosis* rather than the usual 600 mg twice-daily dose used for gram-positive organisms, and clinical investigations are under way. Chemical modification of existing compounds, such as pyrazinamide, may produce new TB drugs. Finally, continuing research on the construction of the mycobacterial cell wall and intracellular pathways may lead to agents with unique activity against this genus.

Liposomes have been investigated as delivery systems for various agents against mycobacteria, including isoniazid, rifampin, and the aminoglycosides. Liposomes also could be used to deliver β-lactams or other agents that generally are excluded from macrophages. By changing the pharmacokinetic profile of such agents, their use in the treatment of mycobacterial infections could be enhanced greatly. Currently, no such product is licensed for use against TB.

Corticosteroids Adjunctive therapy with corticosteroids may be of benefit for some patients with tuberculous meningitis or pericarditis to relieve inflammation and pressure (see Table 121–4).[2,47] They should be avoided in most other circumstances because they detract from the immune response to TB.

Bacille Calmette-Guérin Vaccine The BCG vaccine is an attenuated, hybridized strain of *M. bovis*. It was developed in 1921 and is used as a prophylactic vaccine against TB. Administration of BCG vaccine is compulsory in many developing countries and is officially recommended in many others. Vaccination with BCG produces a subclinical infection resulting in sensitization of T lymphocytes and cross-immunity to *M. tuberculosis*, as well as cutaneous hypersensitivity and, in many cases, a positive tuberculin skin test.

In the published clinical trials, several different BCG preparations were used, and the efficacy of these vaccinations ranged from negative 56% (some patients did worse with the vaccine) to positive 80%.[2,47] Trials within the United States and Puerto Rico have shown efficacy rates of 6% to 29%. The primary benefit of BCG vaccination appears to be the prevention of severe forms of TB in children. Data from the BCG trials show that the incidence of tuberculous meningitis and miliary TB is 52% to 100% lower and that the incidence of pulmonary TB is 2% to 80% lower in vaccinated children younger than 15 years of age than it was in unvaccinated controls.

Unfortunately, BCG does not appear to be very reliable in preventing disease by *M. tuberculosis* in other segments of the population. Side effects occur in 1% to 10% of vaccinated persons and usually include severe or prolonged ulceration at the vaccination site, lymphadenitis, and lupus vulgaris. It is recommended that pregnant women and patients with impaired immune systems, including those with HIV infection, avoid vaccination. The World Health Organization had recommended, however, that in populations where the risk of TB is high, HIV-infected infants who are asymptomatic should receive BCG vaccine at birth or as soon as possible thereafter. Because BCG infection has occurred in AIDS

patients given the vaccine, individuals with symptomatic HIV infection should not be vaccinated.[2,47]

In the United States, BCG vaccination is recommended only for uninfected children who are at unavoidable risk of exposure to TB and for whom other methods of prevention and control have failed or are not feasible.[2,47] Its use is very limited.

PHARMACOECONOMIC CONSIDERATIONS

The World Health Organization and the World Bank agree that the control of TB is one of the most cost-effective health interventions any nation can pursue. Early identification of TB cases and the effective use of isoniazid, rifampin, and pyrazinamide (plus ethambutol) while the isolate is still drug susceptible always should be the primary goals of public health departments. Contact investigation and treatment of those infected but without disease are important secondary goals to reduce the number of future cases.

Patients who complete all their treatment for drug-susceptible TB have cure rates over 95%. Noncompliance (nonadherence), drug resistance, extrapulmonary disease, and concomitant disease states reduce the overall effectiveness of chemotherapy of TB to approximately 75%.

The treatment of TB is not particularly expensive, especially if hospitalization is not required.[96] Furthermore, TB is quite curable. Because the various TB drugs each have a role to play in the treatment of TB or MDR-TB, all the antituberculosis drugs approved by the Food and Drug Administration should be on institutional formularies. Centers that see little MDR-TB need not keep stocks of the second-line drugs, provided that they are readily available should the need arise. Because the treatment of MDR-TB is difficult and because missteps are potentially disastrous, such patients should be referred to centers experienced in the management of MDR-TB.[2,47,97–99]

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING OF THE PHARMACEUTICAL CARE PLAN

The most serious problem with TB therapy is patient nonadherence to the prescribed regimens.[99,100] Unfortunately, there is no reliable way to identify such patients a priori. In the study by Brudney and Dobkin,[99] 89% of the patients were noncompliant with therapy. It is critical to the control of TB that such adherence rates be improved dramatically. The most effective way to achieve this end is with directly observed treatment.[2,14,47] Despite criticisms that it will cost more money, it is far cheaper in the long run to prevent the further spread of disease with directly observed treatment than to track down and treat additional cases of TB continuously.

The homeless and other underprivileged individuals are assumed to constitute the group of patients considered "unreliable," and directly observed treatment should be reserved for them; it is also assumed that "responsible" patients cared for by private physicians may be treated with daily, unsupervised therapy. A study conducted in Baltimore, however, compared outcomes (sputum culture conversion to negative at 3 months) for patients with pulmonary TB who were treated by private physicians with outcomes for patients treated via directly observed treatment in a city-run clinic. Surprisingly, 3-month culture conversion occurred in only 40% of the private-care patients, compared with 90% in the city clinic-care patients.[101] Clearly, expansion of the use of directly observed treatment to nearly all patients with TB may be of benefit.

For patients who are acid-fast bacilli smear positive, they should have sputum samples sent for acid-fast bacilli stains every 1 to 2 weeks until two consecutive smears are negative. This provides early evidence of a response to treatment.[47] Once on maintenance therapy, sputum cultures can be performed monthly until two consecutive cultures are negative, which generally occurs over 2 to 3 months. If sputum cultures continue to be positive after 2 months, drug susceptibility testing should be repeated, and serum concentrations of the drugs should be checked.

Serum chemistries, including blood urea nitrogen, creatinine, aspartate transaminase, and alanine transaminase, and a complete blood count with platelets should be performed at baseline and periodically thereafter, depending on the presence of other factors that may increase the likelihood of toxicity (e.g., advanced age, alcohol abuse, pregnancy).[2,47] Hepatotoxicity should be suspected for patients whose transaminases exceed five times the upper limit of normal or whose total bilirubin concentration exceeds 3 mg/dL and for patients with symptoms such as nausea, vomiting, or jaundice. At this point, the offending agent(s) should be discontinued. Sequential reintroduction of the drugs with frequent testing of liver enzymes is often successful in identifying the offending agent; other agents may be continued. Alternative agents should be selected as needed. Audiometric testing should be performed at baseline and monthly for patients who must receive aminoglycosides for more than 1 to 2 months. Vision testing (Snellen visual acuity charts and Ishihara color discrimination plates) should be performed on all patients who receive ethambutol. All patients diagnosed with TB should be tested for HIV infection.

THERAPEUTIC DRUG MONITORING

Therapeutic drug monitoring (TDM), or applied pharmacokinetics, is the use of serum drug concentrations to optimize therapy.[47,51,53,101] Non-AIDS patients with drug-susceptible TB generally do well, and TDM generally should be used if they are failing appropriate directly observed treatment (no clinical improvement after 2 to 4 weeks or smear positive after 4 to 6 weeks). On the other hand, patients with AIDS, diabetes, cystic fibrosis, and various gastrointestinal disorders often fail to absorb these drugs properly and are candidates for TDM. Furthermore, patients with hepatic or renal disease should be monitored, given their potential for overdoses.

CLINICAL CONTROVERSY

Some TB centers employ TDM for many of their patients at the outset of treatment in order to identify drug-delivery problems early. Other centers wait to see how the patient responds and perform TDM only if problems arise. An argument can be made for either approach. The latter can save money, but delays in effective treatment can affect the patient's outcome adversely. Most otherwise healthy TB patients will absorb their drugs adequately. Patients who are critically ill or who have MDR-TB can benefit from early TDM.

In the treatment of MDR-TB, the differences between the maximum serum concentration (C_{max}) and the MIC for the second-line agents are much smaller that with isoniazid and rifampin. Therefore, alterations in the absorption of these drugs can have significant impact on the outcome of therapy.[51,53] Although the optimal serum concentrations for TB are not known, target serum peak concentrations have been proposed.[51,53] Blood samples collected at 2 and 6 hours after a dose have been used with some success, although they may not be the optimal sampling times for all the

drugs. Long–half-life drugs (e.g., pyrazinamide and cycloserine) can be sampled at 2 and 10 hours if an estimate of the half-life is desired. Finally, TDM of the TB and HIV drugs is perhaps the most logical way to untangle the complex drug interactions that take place (see Table 121–7).[103,104]

CONCLUSIONS

Good patient adherence to treatment regimens is the cornerstone to effective antimycobacterial chemotherapy. Pharmacists should monitor TB therapy with particular interest in drug–drug interactions, drug malabsorption, and avoiding the error of adding a single drug to a failing regimen. They should educate patients on the importance of continuing their chemotherapy despite symptomatic improvement. Pharmacists should become part of a multidisciplinary team (with nurses, physicians, and social workers) devoted to successful chemotherapy of TB patients and their families.

ABBREVIATIONS

ATS: American Thoracic Society

BCG: bacillus Calmette-Guérin

CDC: Centers for Disease Control and Prevention

CMI: cell-mediated Immunity

DTH: delayed-type hypersensitivity

IGRA: interferon gamma release assay

INF: interferon

CHAPTER 122

Gastrointestinal Infections and Enterotoxigenic Poisonings

STEVEN MARTIN AND ROSE JUNG

KEY CONCEPTS

1. The etiology of infectious diarrhea includes bacteria, viruses, and protozoans. Viral infections are the leading cause of diarrhea in the world.
2. Fluid and electrolyte replacement is the cornerstone of therapy. Oral rehydration therapy is preferred in most cases of mild and moderate diarrhea. The necessary components of oral replacement therapy are glucose, sodium, potassium, chloride, and water.
3. Antimicrobial therapy often is not indicated for enteritis because many cases are mild and self-limited or are viral in nature.
4. Diarrheal illness can be prevented by following simple rules of personal hygiene and safe food preparation.
5. The most common pathogens for traveler's diarrhea include enterotoxigenic *Escherichia coli*, *Shigella*, *Campylobacter, Salmonella*, and viruses.
6. Patient education in prevention strategies and self-treatment of traveler's diarrhea is recommended. Prophylaxis with antibiotics is not recommended in most situations.
7. Common pathogens responsible for food poisoning include *Staphylococcus, Salmonella, Shigella,* and *Clostridium.*

Gastrointestinal (GI) infections encompass a wide variety of syndromes from mild gastroenteritis to life-threatening systemic disease. Dehydration from GI infections is the second leading cause of morbidity and mortality worldwide, and infants and children younger than age 5 years are at the highest risk. From 1992 to 2000, the median incidence of diarrhea for all children younger than age 5 years was 3.2 episodes per child per year. The incidence of diarrhea was higher in younger children, with 4.8 episodes per child per year among children ages 6 to 11 months, compared with 1.4 episodes per child per year for children age 4 years. Younger children also had a higher risk of death from acute dehydrating diarrhea. For children younger than age 1 year and those age 1 to 4 years, the median mortality rates were 8.5 and 3.8 per 1,000 children per year, respectively.[1] Although this was a decrease from 13.6 per 1,000 children per year during 1955–1979 and 5.6 per 1,000 children per year during 1980 to 1989, diarrhea remains a major health problem in children, especially in those younger than age 1 year.[2,3]

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Although outbreaks of infectious diarrhea and deaths in the United States are not as common as in other parts of the world, the economic burden of GI infections still remains high. The estimates by the Centers for Disease Control and Prevention (CDC) suggest that 211 million episodes of acute gastroenteritis occur each year in the United States, resulting in more than 900,000 hospitalizations and more than 6,000 deaths. In contrast to the developing world, where the risk of death is highest among young children, in the United States, most of those who die of diarrheal illness are elderly. According to the National Center for Health Statistics, during 1979 to 1987, 51% of deaths caused by diarrheal illness were among patients older than age 74 years, and 27% were among the ages of 55 to 74 years; only 11% of deaths were in those younger than age 5 years.[2] Similarly, a study of the McDonnell-Douglas Health Information System database revealed that 25% of all hospitalizations and 85% of all mortality associated with diarrhea involved the elderly (≥age 60 years).[3] In addition to children and elderly, other groups at risk for GI infections include travelers and campers, patients in chronic care facilities, military personnel assigned overseas, and immunocompromised patients such as those with acquired immunodeficiency syndrome (AIDS).

Fortunately, diarrheal mortality has declined substantially in the past two decades, especially among children younger than age 1 year. Interventions for diarrheal disease such as breast-feeding, better weaning practices, improved sanitation, and increased use of oral rehydration therapy are responsible for the decrease in case-fatality rates. Although this reduction in mortality is reassuring, diarrhea still remains among the top 10 leading causes of death world wide.[4] To achieve further declines in mortality, a more complex approach needs to be adopted that includes distinguishing acute watery diarrhea from dysentery and persistent diarrhea, and providing appropriate case management for each syndrome.

1 A variety of pathogens are responsible for acute infectious diarrhea. Viruses are suspected to be the most common cause of gastroenteritis worldwide, especially in children. However, in the United States, bacterial species are the most commonly identified cause of infectious diarrhea. This chapter focuses on the bacterial and viral etiologies of GI infections such as *Vibrio cholerae*, *Escherichia coli, Salmonella, Shigella, Campylobacter jejuni*, rotaviruses, noroviruses, astrovirus, and enteric adenovirus. Clinical presentation, diagnosis, treatment, and prevention strategies are discussed in general terms initially for all GI infections, and further elaborated in regards to specific etiologies in subsequent sections.

CLINICAL PRESENTATION AND DIAGNOSIS

Gastroenteritis is an illness characterized by diarrhea which may be accompanied by nausea, vomiting, fever, and abdominal pain.[5] Diarrhea is usually defined as a decrease in consistency of bowel movements (i.e., unformed stool) and an increase of stools to ≥3 per day. For best diagnosis and management, it is important to distinguish secretory diarrhea that produces watery diarrhea from inflammatory diarrhea. Caused by invasive pathogens, inflammatory diarrhea often presents as fever, tenesmus, or bloody stool. Symptoms of and enteric pathogens that cause watery and inflammatory diarrhea are listed in Table 122–1.

A careful history and physical examination that includes information about symptoms, the length of time the patient has been sick, the number of individuals affected, and recent history of travel, diet, and medications are important factors in making a diagnosis. Stool cultures are also an invaluable tool in making an organism-specific diagnosis and determining sensitivity to antimicrobial agents. The stool culture will identify the presence of *Campylobacter, Salmonella,* and *Shigella* species. Other pathogens such as *Yersinia* and *Vibrio* species may also be detected using selective media. Unfortunately, the yield of positive stool cultures is very low. In order to improve the usefulness of stool cultures, fecal testing is recommended in patients with inflammatory diarrhea.[5] For community-acquired or traveler's diarrhea, stool samples should be sent for culture of *Salmonella, Shigella,* and *Campylobacter,* and toxin testing of *E. coli* O157:H7 and *C. difficile* toxins A and B. In hospitalized patients who develop diarrhea 3 days after hospitalization, stool specimen should be tested for *C. difficile* toxins A and B, especially in those who are exposed to antimicrobial therapy or chemotherapy. Stool culture is also recommended in patients with persistent diarrhea, especially if they are immunocompromised (i.e., persons age 65 years and older with comorbid diseases, neutropenia, or human immunodeficiency virus [HIV] infection). In immunocompromised hosts, a wide range of viral, bacterial, and parasitic organisms should be sought. In addition to stool cultures, microscopic examination for fecal polymorphonuclear cells, or a simple immunoassay for the neutrophil marker lactoferrin can further provide evidence of an inflammatory process and increase the yield of cultures for invasive pathogens in patients presenting with fever or bloody stool.

TABLE 122-1 Acute Infectious Diarrhea Clinical Syndromes: Watery vs. Inflammatory

	Watery	Inflammatory
Percentage of patients	90	5–10
Stools		
Appearance	Watery	Bloody
Volume	Increased: ++/+++	Increased: +/++
Number per day	<10	>10
Reducing substances	0 to +++	0
pH	5.0–7.5	6.0–7.5
Occult blood	Negative	Positive
Fecal polymorphonuclear cells	Absent or few	Many
Mechanisms	Toxins Reduced absorption	Mucosal invasion
Complications		
Dehydration	Could be severe	Mild
Others	Acidosis, shock, electrolyte imbalance	Tenesmus, rectal pro-lapse, seizures
Etiology	*Vibrio cholerae* Enterotoxigenic *Escherichia coli* (ETEC) Enteropathogenic *E. coli* (EPEC) Rotaviruses Noroviruses	*Shigella* *Salmonella* *Campylobacter* *Yersinia* Enterohemorrhagic *E. coli* (EHEC) Enteroinvasive *E. coli* (EIEC) Enteroaggregative *E. coli* (EAEC) *Cytotoxigenic C. difficile*

TREATMENT

Diarrhea

GENERAL APPROACHES TO MANAGEMENT

Rehydration Therapy

Initial assessment of fluid loss is essential for rehydration and should include acute weight loss, as it is the most reliable means of determining the extent of water loss. However, if accurate baseline weight is not available, clinical signs are helpful in determining approximate deficits (Table 122–2).[6,7] Physical assessment generally is more reliable in young children and infants than in adults.

2 Fluid replacement is the cornerstone of therapy for dehydration due to diarrhea regardless of etiology. For the treatment of mild to moderate dehydration, oral rehydration therapy (ORT) is superior to administration of intravenous (IV) fluids. ORT reverses dehydration in nearly all patients with mild to moderate diarrhea with 94% to 97% efficacy.[6] ORT offers the advantages of being inexpensive, noninvasive, and does not require hospitalization for administration. Moreover, thirst drives use of ORT and provides a safeguard against overhydration.

The necessary components of oral rehydration solutions (ORS) include carbohydrates (typically glucose), sodium, potassium, chloride, and water. Glucose-based ORS takes advantage of glucose-coupled sodium transport in the small bowel that enhances sodium and subsequently water transport across intestinal walls. In 2002, the World Health Organization/United Nations Children's Fund (WHO/UNICEF) recommended a reduced osmolarity solution (Osm = 245 mmol/L) for ORT in response to reports that this reduced osmolarity solution reduced stool output, vomiting, and the need for intravenous therapy.[7] The composition of commercial ORS and commonly consumed beverages are listed in Table 122–3.[8] Clear fluids, such as soft drinks, sweetened fruit drinks, broth, and sports drinks should be avoided in the treatment of dehydration. Those solutions may cause an osmotic diarrhea and hypernatremia.

In the treatment of severe dehydration, IV therapy remains the therapy of choice. Severely dehydrated patients should be resuscitated initially with Lactated Ringer's solution or normal saline intravenously to restore hemodynamic stability. Lactated Ringer's solution is preferred over normal saline because normal saline does not correct metabolic acidosis. Rapid IV rehydration is preferred over more prolonged replacement regimens for restoring extracellular fluids and electrolytes because it more effectively reestablishes gastrointestinal and renal perfusion. ORT should be instituted as soon as it can be tolerated.

Treatment of dehydration consists of rehydration, replacement of ongoing losses, and continuation of normal feeding. Guidelines on rehydration therapy based on degree of dehydration and replacement of ongoing losses are outlined in Table 122–2. ORS should be given in small and frequent volumes (5 mL every 2 to 3 minutes in a teaspoon or oral syringe). Nasogastric administration of ORT is

TABLE 122-2 Clinical Assessment of Degree of Dehydration in Children Based on Percentage of Body Weight Loss[a]

Variable	Minimal or No Dehydration (<3% Loss of Body Weight)	Mild to Moderate (3–9% Loss of Body Weight)	Severe (≥10% Loss of Body Weight
Blood pressure	Normal	Normal	Normal to reduced
Quality of pulses	Normal	Normal or slightly decreased	Weak, thready, or not palpable
Heart rate	Normal	Normal to increased	Increased (bradycardia in severe cases)
Breathing	Normal	Normal to fast	Deep
Mental status	Normal	Normal to listless	Apathetic, lethargic, or comatose
Eyes	Normal	Sunken orbits/decreased tears	Deeply sunken orbits/absent tears
Mouth and tongue	Moist	Dry	Parched
Thirst	Normal	Eager to drink	Drinks poorly; too lethargic to drink
Skin fold	Normal	Recoil in <2 seconds	Recoil in >2 seconds
Extremities	Warm, normal capillary refill	Cool, prolonged capillary refill	Cold, mottled, cyanotic, prolonged capillary refill
Urine output	Normal to decreased	Decreased	Minimal
Hydration therapy	None	ORS 50–100 mL/kg over 3–4 hours	Lactated Ringer's solution or normal saline 20 mL/kg in 15–30 minutes intravenously until mental status or perfusion improve; Followed by 5% dextrose ½ normal saline intravenously at twice maintenance rates or ORS 100 mL/kg over 4 hours.
Replacement of ongoing losses	<10kg body weight: 60–120 mL ORS per >10kg body weight: 120–240 mL ORS per diarrheal stool or emesis	Same	If unable to tolerate ORS, administer through nasogastric tube or administer 5% dextrose ½ normal saline with 20 mEq/L potassium chloride intravenously

ORS, oral rehydration solution.
[a]Percentages vary among authors for each dehydration category; hemodynamic and perfusion status is most important; when unsure of category, therapy for more severe category is recommended.
Data from King et al. (6) and World Health Organization (7)

an alternative method of administration in a child with persistent vomiting. For breastfed infants, nursing should be continued.

Early refeeding as tolerated is recommended.[6,7] Age-appropriate unrestricted diet is recommended as soon as dehydration is corrected. Early initiation of feeding can shorten the course of diarrhea. In a study of severely malnourished children with diarrhea younger than age 5 years, the use of a standardized protocol of slow oral rehydration, immediate feeding, and intensive management of complications resulted in a significant reduction of mortality as compared with standard therapy. Initially, easily digested foods such as bananas, applesauce, and cereal may be added. Foods high in fiber, sodium, and sugar should be avoided. Lactase deficiency may be exacerbated among known lactase-deficient patients and may persist up to 10 days.

Antimicrobial Therapy

The indiscriminate use of antimicrobial therapy in GI infections produces increases in antimicrobial resistance, side effects of antimicrobial agents, and the threat of superinfections owing to eradication of normal flora. Increasing fluoroquinolone resistance in *Campylobacter* and multidrug resistance in *Salmonella* species worldwide reinforce the importance of judicious use of antibiotics and prudent infection control measures.[9,10] Furthermore, it is important to take local susceptibility patterns into consideration in the selection of initial therapy with an antimicrobial regimen.

3 Antibiotics are not essential in the treatment of most mild diarrheas, and empirical therapy for acute GI infections may result in courses of unnecessary antibiotics. However, appropriate antibiotic therapy shortens the duration of illness and reduces morbidity in some bacterial (cholera, enterotoxigenic *E. coli*, shigellosis, campylobacteriosis, yersiniosis) infections and can be lifesaving in invasive infections (*C. difficile*, salmonellosis). Antibiotic treatment also reduces the duration and shedding of organisms in infections with susceptible *Shigella* species and possibly in infection with susceptible *Campylobacter* species. Table 122–4 summarizes antibiotic recommendations. Further details regarding treatment of specific infections are discussed in appropriate sections.

It is also important to note that outcomes of some bacterial diarrheal illnesses may be worsened by the use of antibiotics. Antibiotic treatment may prolong asymptomatic carriage of *Salmonella*.[11] In patients infected with *E. coli* O157, use of an antimicrobial agent may worsen the risk of hemolytic uremic syndrome (HUS), which is defined by the triad of acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia, by increasing the production of shiga-like toxin.[12]

TABLE 122-3 Comparison of Common Solutions Used in Oral Rehydration and Maintenance

Product	Na (mEq/L)	K (mEq/L)	Base (mEq/L)	Carbohydrate (mmol/L)	Osmolality (mOsm/L)

TABLE 122-4 Recommendations for Antibiotic Therapy

Pathogen	First-Line Agents	Alternative Agents
Enterotoxigenic (cholera-like) diarrhea		
Vibrio cholerae O1 or O139	Doxycycline 300 mg orally × 1	Tetracycline 500 mg orally four times daily × 3 days; ciprofloxacin 500 mg orally every 12 hours × 3 days or 1 g orally single dose; norfloxacin 400 mg orally every 12 hours × 3 days; levofloxacin 500 mg orally once daily × 3 days; trimethoprim-sulfamethoxazole DS tablet twice daily × 3 days; erythromycin 250–500 mg orally every 6–8 hours; azithromycin 1,000 mg orally × 1
Enterotoxigenic *Escherichia coli*	Ciprofloxacin 500 mg orally every 12 hours, norfloxacin 400 mg orally every 12 hours, levofloxacin 500 mg orally once daily × 3 days	Rifaximin 200 mg 3 times daily × 3 days; azithromycin 1,000 mg orally × 1 or 500 mg orally daily × 3 days
Invasive (dysentery-like) diarrhea		
Shigella species[a]	Ciprofloxacin 500 mg orally every 12 hours, norfloxacin 400 mg orally every 12 hours, levofloxacin 500 mg orally 1 daily × 5 days	Azithromycin 500 mg orally × 1, then 250 mg orally daily × 4 days
Salmonella		
Nontyphoidal[a]	Gastroenteritis: Ciprofloxacin 500 mg every 12 hours × 5–7 days Bacteremia: Ceftriaxone 2 g IV daily × 7–14 days Chronic carriers: Ciprofloxacin 750 mg orally every 12 hours × 1 month	Gastroenteritis: Azithromycin 1,000 mg orally × 1 day, followed by 500 mg orally once daily × 6 days; trimethoprim-sulfamethoxazole DS orally every 12 hours × 5–7 days Chronic carriers: amoxicillin 1,000 mg orally every 8 hours × 3 months; trimethoprim-sulfamethoxazole DS orally every 12 hours × 3 months
Campylobacter[a]	Erythromycin 500 mg orally twice daily, azithromycin 1,000 mg orally × 1 day followed by 500 mg daily or clarithromycin 500 mg orally twice daily × 5 days	Ciprofloxacin 500 mg or norfloxacin 400 mg orally twice daily × 5 days
Yersinia species[a]	A combination therapy with doxycycline, aminoglycosides, trimethoprim-sulfamethoxazole, or fluoroquinolones	
Clostridium difficile	Mild to moderate disease: Metronidazole 250 mg every 6 hours to 500 mg every 8 hours orally or intravenously daily × 10–14 days Severe disease: Vancomycin 125 mg every 6 hours orally × 10–14 days First relapse: same as above Subsequent relapses: Tapered pulse dose of oral vancomycin (125 mg every 6 hours × 2 weeks, every 12 hours × 1 week, every 24 hours × 1 week, every 48 hours × 8 days (4 doses), every 72 hours × 15 days (5 doses)	Subsequent relapses: Oral vancomycin 125 mg every 6 hours × 10–14 days followed by rifaximin 400 mg every 12 hours orally × 2 weeks; Nitazoxanide 500 mg every 12 hours × 10 days
Traveler's diarrhea		
Prophylaxis[a]	Norfloxacin 400 mg or ciprofloxacin 750 mg orally daily	Rifaximin 200 mg one to three times daily up to 2 weeks
Treatment	Norfloxacin 800 mg orally × 1 or 400 mg orally every 12 hours × 3 days, or Ciprofloxacin 750 mg orally ×1 or 500 mg orally every 12 hours × 3 days, or Levofloxacin 1,000 mg orally × 1 or 500 mg orally daily × 3 days Azithromycin 1,000 mg orally × 1 or 500 mg orally daily × 3 days	Rifaximin 200 mg 3 times daily × 3 days

[a]For high-risk patients only. See the preceding text for the high-risk patients in each infection.

Antimotility Agents

Antiperistaltic drugs such as diphenoxylate and loperamide offer symptomatic relief in patients with mild diarrhea. However, these agents are contraindicated in most toxin-mediated diarrheal illnesses (enterohemorrhagic *E. coli*, pseudomembranous colitis, shigellosis) and thus should be avoided in patients with high fever and bloody diarrhea. Slowing of fecal transit time is thought to result in extended toxin-associated damage, worsening diseases such as HUS.

CLINICAL CONTROVERSY

Loperamide should not be used in patients with fever or bloody stool. There is evidence that the use of such agents can increase the risk for development of HUS, possibly by delaying intestinal clearance of the organism and thereby increasing toxin absorption.

PREVENTION OF GASTROINTESTINAL INFECTIONS

4 Public health measures of improved water supply and sanitation facilities and the quality control of commercial products are important for the control of the majority of enteric infections. In addition, many diarrheal diseases can be prevented by following simple rules of personal hygiene and safe food preparation. Handwashing with soap and running water is instrumental in preventing the spread of illness and should be emphasized for caregivers and persons with diarrheal illnesses. Safe food handling and preparation practices can significantly decrease the incidence of certain types of enteric infections.

Reporting suspected outbreaks and cases of notifiable illness to local health authorities is vital in investigation of threats of enteric infection arising from increasingly global and industrialized food supplies. The reporting of specific infectious diseases to the appropriate public health authorities is the cornerstone of public health surveillance, outbreak detection, and prevention and control efforts.

Vaccines are used to boost specific immune processes directed against the bacteria themselves or against adherence appendages, cytotoxins, or enterotoxins. Unfortunately, there are only a few vaccines available for prevention of gastroenteritis. Currently available vaccines for typhoid fever are the parenteral Vi capsular polysaccharide vaccine and the oral live-attenuated Ty21a vaccine.[13] Efficacy rates for both vaccines range from 50% to 80%. There are 2 vaccines (RotaTeq and Rotarix) available for reducing rotaviral gastroenteritis.[14]

PATIENT ASSESSMENT

Appropriate follow-up care of patients with acute diarrhea is based on successful restoration of fluid losses. The clinical signs and symptoms (see Table 122–1) that lead to the diagnosis also can assess adequate rehydration, and should be monitored frequently. Since oral rehydration therapy is now preferred, routine laboratory testing often is unnecessary. Electrolytes should be measured in those receiving IV fluids, when oral replacement fails, or when signs of hypernatremia or hypokalemia are present. Follow-up stool samples to ensure complete evacuation of the infecting pathogen may be necessary only in patients who are at high risk to initiate or contribute to a community outbreak. All patients should be monitored for complications associated with the infecting pathogen, resolution of the diarrhea, and adverse reactions to the pharmacologic agents used. Prompt discharge of hospitalized patients is recommended when rehydration is achieved, intravenous fluids have not been required, oral intake equals or exceeds losses, or adequate education and medical follow-up are ensured. For most patients, discharge can occur in 16 to 24 hours.

SPECIFIC BACTERIAL INFECTIONS

Bacterial agents are important causes of GI infections, and syndromes caused by these pathogens are better understood than viral gastroenteritis. For a simple generalization, the bacterial pathogens presented in this section are divided into either those that cause watery (enterotoxigenic) diarrhea or those that cause dysentery (invasive diarrhea). Watery diarrhea is usually self-limiting, whereas those who present with dysenteric symptoms, such as fever, tenesmus, and blood and/or pus in the stool, require close monitoring and intensive follow-up. Table 122–1 lists the clinical signs and symptoms of these two broad categories.

WATERY (CHOLERA-LIKE) DIARRHEA

Cholera (*Vibrio Cholerae*)

Epidemiology Cholera has been endemic in the Ganges delta, West Bengal, Bangladesh, and southern Asia (including Southeast Asia) since at least 1817. A 1994 outbreak of a multidrug-resistant strain of cholera among Rwandan refugees resulted in more than 20,000 deaths. Cholera epidemics in 1991 and 1998 caused more than 1 million deaths in Latin America. As international travel has increased, cholera has also been reported in all major regions of the United States. However, the incidence, 1 case per 1 million persons, is extremely low.[15]

V. cholerae O1 is the most common serogroup associated with epidemics and pandemics. Within this serogroup, there are two biotypes, classic and El Tor.[16] In 1992, a new serogroup, *V. cholerae* O139 Bengal, appeared in India and spread rapidly through Southeast Asia. Four mechanisms for transmission have been proposed, including animal reservoirs, chronic carriers, asymptomatic or mild disease victims, and water reservoirs.

A relatively large inoculum of 10^3 to 10^6 organisms is required for infection if water is the vehicle, and 10^2 to 10^4 if the vehicle is food. Approximately half of the people infected with *V. cholerae* O1 are symptomatic, whereas only 1% to 5% of those infected with *V. cholerae* O139 manifest symptoms. The hallmark of cholera is the production of profuse, watery diarrhea, and severe dehydration may develop within a few hours, causing death within 24 hours. An estimated 25% to 50% of cases are fatal if left untreated. The prevention of cholera transmission depends on the provision of clean drinking water and public sanitation, which is difficult in impoverished and developing countries.[17]

Pathogenesis *V. cholerae* is a gram-negative bacillus sharing similar characteristics with the family Enterobacteriaceae. Most pathology of cholera results from an enterotoxin (cholera toxin) produced by the bacteria.[17] Conditions that reduce gastric acidity, such as the use of antacids, histamine receptor blockers, or proton pump inhibitors, or infections with *Helicobacter pylori,* increase the risk for clinical disease. Cholera toxin stimulates adenylate cyclase, which increases intracellular cyclic adenosine monophosphate (cAMP) and results in inhibition of sodium and chloride absorption by microvilli and promotes the secretion of chloride and water by crypt cells. The toxin likely acts along the entire intestinal tract, but most fluid loss occurs in the duodenum. The net effect of the cholera toxin is isotonic fluid secretion (primarily in the small intestine) that exceeds the absorptive capacity of the intestinal tract (primarily the colon). This results in the production of watery diarrhea with electrolyte concentrations similar to that of plasma.

Clinical Presentation The average incubation period for *V. cholerae* infection is 1 to 3 days.[17] The clinical presentation can vary from asymptomatic to life-threatening dehydration owing to watery diarrhea. Patients may lose up to 1 L of isotonic fluid every hour. The onset of diarrhea is abrupt and is followed rapidly or sometimes preceded by vomiting. Fever occurs in less than 5% of patients, and the physical examination correlates well with the severity of dehydration. In some cases, fluid accumulates within the intestinal lumen causing abdominal distension and ileus and may cause intravascular depletion without diarrhea. In the most severe state, this disease can progress to death in 2 to 4 hours if not treated.

Laboratory abnormalities, such as increased packed red blood cell volume and total protein, magnesium, and calcium levels, are a result of hemoconcentration. Hypoglycemia, seizures, fever, and mental alterations are seen more often in children, perhaps as a reflection of the greater degree of dehydration and electrolyte losses observed with diarrhea in children. Other complications include metabolic acidosis, prerenal azotemia, iatrogenic water intoxication from overhydration, and aspiration pneumonia. Children, the elderly, and pregnant women are at an increased risk of complications caused by cholera.

TREATMENT

Regardless of the serotypes, the primary goal of therapy is rapid restoration of fluid losses, correction of metabolic acidosis, and replacement of potassium deficiency. In restoring fluid and electrolyte balance in cholera infections, rice-based ORT may be more efficacious than glucose-based ORT, reducing fluid requirements by 32% to 35% when rice-based instead of glucose-based ORT solutions are used (50 to 80 grams rice instead of 20 grams glucose/L).[18] In patients who cannot tolerate ORT, lactated Ringer's solution IV is preferred. After rehydration, maintenance fluid is given based on accurate recording of intake and output volumes.

Antibiotics are not necessary in most cholera cases. However, in severe cases, antibiotics shorten the duration of diarrhea, decrease

fluid loss, and shorten the duration of the carrier state.[17] There appears to be substantial mobility in genetic elements encoding antibiotic resistance in *V. cholerae*, and the drug resistance patterns may change between outbreaks. For example, O139 strains isolated during 1992 and 1993 showed a trend toward increased resistance to trimethoprim-sulfamethoxazole, but those isolated in India during 1996 and 1997 showed susceptibility to the same agent. A single dose of doxycycline is the preferred agent, especially in endemic areas, although it has been associated with prolonged fecal excretion of bacteria.[11] In areas of high tetracycline resistance, fluoroquinolones such as ciprofloxacin are effective, and in areas of high fluoroquinolone resistance, azithromycin has been shown to be effective.[19] In children and pregnant women, erythromycin and azithromycin can be used.[20]

The manufacture of the only licensed whole-cell cholera vaccine in the United States has been discontinued. Two oral vaccines are available in other countries.[17] Dukoral consists of killed *V. cholerae* organisms and the cholera B subunit, and Orochol is an avirulent mutant of *V. cholerae* strain CVD103HgR. Both vaccines are effective in field trials and volunteer studies, but their cost-effectiveness in endemic settings is uncertain. The World Health Organization (WHO) does not require vaccination for international travel to or from endemic areas because the series of two injections is effective in only 50% of people and immunity wanes in 6 months or less.

Escherichia Coli

Diarrheagenic *E. coli* is differentiated into several distinct categories based on pathogenic features of diarrheal disease: enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteropathogenic *E. coli* (EPEC), enteroaggregative *E. coli* (EAEC), and enterohemorrhagic *E. coli* (EHEC). The most common diarrheagenic *E. coli* infection is caused by ETEC manifested by watery (enterotoxigenic) diarrhea. Dysentery is caused by EHEC. In this section, commonly known categories of diarrheagenic *E. coli* that cause watery diarrhea are discussed separately from EHEC that cause bloody diarrhea.

Epidemiology ETEC occurs most commonly, and accounts for about half of all cases of *E. coli* diarrhea. There are an estimated 79,420 cases in the United States each year.[21] TEC is the most common cause of traveler's diarrhea and a common cause of food- and water-associated outbreaks. Infections with EIEC and EPEC are primarily a disease of children in developing countries.[22,23] EAEC strains are implicated in persistent diarrhea (≥14 days) in HIV-infected patients.[24]

Recognized as a common and potentially deadly cause of infectious diarrhea, EHEC is believed to be the major etiologic factor responsible for the development of hemorrhagic colitis and HUS. The CDC estimates the annual disease burden of *E. coli* O157:H7 in the United States to be more than 20,000 infections and as many as 250 deaths, but the failure of many clinical laboratories to screen for this organism greatly complicates any estimates.[25] In the United States, serotype O157:H7 causes 50% to 80% of all EHEC infections, but in the southern hemisphere, such as in Argentina, Australia, Chile, and South Africa, non-O157:H7 serotypes are often more important. Transmission usually occurs via food and water, and outbreaks have been associated with undercooked ground beef and feces-contaminated vegetables.

Pathogenesis *E. coli* is a gram-negative bacillus commonly found in the human GI tract as well as in intestines of healthy cattle, deer, goats, and sheep. Enterotoxigenic *E. coli* are capable of producing either or both plasmid-mediated enterotoxins: heat-labile toxin and heat-stable toxin.[21] A cholera-like toxin, heat-labile toxin has two subunits (A and B) that have similar antigenic properties and action on the gut mucosa. The net effect is luminal accumulation of electrolytes that draws water into the intestine, and production of a cholera-like secretory diarrhea. Heat-stable toxin is nonantigenic and produces watery diarrhea by acting on the small intestine.

The mode of pathogenesis of the non-ETEC varieties is less well understood. The hallmark histopathologic lesions of EPEC infections is the effacing of microvilli and intimate adherence between the bacterium and the epithelial cell membrane throughout the intestine.[23] The attaching and effacing lesions disrupt the integrity of the intestinal epithelium, leading to diarrhea. EAEC adheres to intestinal mucosal cells by mucus production and deposition of bacteria in a bacterium–mucus biofilm.[24] This persistent colonization of EAEC potentially leads to cytotoxic damage of intestinal cells, resulting in persistent diarrhea. EIEC closely resembles *Shigella* species and penetrates the intestinal mucosa, predominantly the lining of the large intestine. The resulting histological damage is inflammation and mucosal ulceration which are characteristic of bacillary dystentery.[22]

The pathogenicity of EHEC is related to the production of shiga-like toxins, so named because of their resemblance to the shiga toxin of *Shigella dysenteriae*.[25] The cytotoxic effect of shiga-like toxins disrupts the mucosal integrity of the large intestine, causing diarrhea. In addition, the toxin is able to pass through the intestinal epithelium to reach the endothelial cells lining small blood vessels that supply the gut, kidney, and other viscera, causing the myriad metabolic events that eventually lead to HUS.

Clinical Presentation Nausea and watery stools, with or without abdominal cramping, are characteristic of the disease caused by ETEC. Usually there is no blood or pus in the stool. Signs and symptoms depend directly on the extent of fluid loss, which in most cases is subclinical. Most ETEC diarrhea is typically abrupt in onset and resolves within 24 to 48 hours without complication. Common symptoms of EPEC infection include acute onset of profuse watery diarrhea, vomiting, and low-grade fever. The clinical features of EAEC diarrhea are characterized as persistent, watery, mucoid, secretory diarrhea with low-grade fever and little or no vomiting. EIEC infection presents most commonly as watery diarrhea, which can be indistinguishable from the secretory diarrhea seen with ETEC. However, in a minority of cases, patients experience the dysentery syndrome, manifested as blood, mucus, and leukocytes in the stool with tenesmus and fever.

Symptoms from EHEC infection can be severe, with as many as 12 bloody stools per day.[22] Initially, EHEC infections typically manifest as cramping abdominal pain, abdominal distension, and watery diarrhea. Nausea occurs in about two-thirds of patients, and vomiting occurs in less than half. The white blood cell count is elevated and accompanied by a left shift, but patients often remain afebrile. Within 1 to 2 days the diarrhea becomes bloody with increased abdominal pain. The illness typically resolves in 1 week; however in approximately 2% to 7% of cases, particularly in children younger than age 5 years and the elderly, the disease is complicated by development of HUS. Death may occur rarely, usually as a result of HUS.[25]

TREATMENT

The cornerstone of management of all diarrheagenic *E. coli* infection is to prevent dehydration by correcting fluid and electrolyte imbalances. ORT is often lifesaving in infants and children.[21] Although antimicrobial prophylaxis is effective in preventing ETEC diarrhea, the growing problem of antibiotic resistance and the possibility of adverse effects from antimicrobial agents deter recommendations of prophylaxis. Instead, recommendations involve avoiding risk factors while traveling. In addition, loperamide and to a lesser extent, bismuth subsalicylate, are effective in decreasing

the severity of ETEC diarrhea; empirical antibiotics shorten the duration of the disease. Fluoroquinolones (e.g., ciprofloxacin, norfloxacin, and levofloxacin) are the most commonly recommended agents owing to increasing antimicrobial resistance among other drug classes.[21]

The use of antibiotics remains controversial in EHEC infection.[25] Their use may be harmful because of lysis of bacteria leading to increased release of toxin and alteration of normal intracolonic bacterial flora, thereby increasing the systemic absorption of the toxin. Treatment of EHEC infection is primarily limited to supportive care, which may include dialysis, hemofiltration, transfusion of packed erythrocytes, platelet infusions, and other interventions as indicated clinically.[25] Severe disease may cause chronic kidney failure and require renal transplant.

INFLAMMATORY (DYSENTERY-LIKE) DIARRHEA

Bacillary Dysentery (Shigellosis)

Epidemiology Approximately 450,000 cases of shigellosis occur in the United States and 165 million cases occur in the world annually, resulting in more than 1 million global deaths each year.[26] Shigellosis is primarily a disease of children, with the highest incidence in children between the ages of 6 months and 5 years. Only a third of all cases occur in adults. Most cases result from fecal–oral transmission. A few well-documented food- and water-associated outbreaks have been reported. The peak incidence in the United States is in late summer.

The shigellae have worldwide distribution, with regional differences in prevalence of subgroups responsible for disease. Four species most often associated with disease are *S. dysenteriae* type I, *Shigella flexneri, Shigella boydii,* and *Shigella sonnei.*[26] In the United States, the common causes of shigellosis are *S. sonnei* and *S. flexneri.* Cases caused by other shigellae are commonly acquired during travel to developing countries. Because of overuse of antibiotics in human and animal feed, Southeast Asia and India have higher levels of resistance. Poor sanitation, poor personal hygiene, inadequate water supply, malnutrition, and increased population density are associated with an increased risk of *Shigella* gastroenteritis epidemics, even in developed countries.

Pathogenesis The shigellae are gram-negative bacilli belonging to the family Enterobacteriaceae. Ingestion of as few as 10 to 200 viable organisms of the *Shigella* species causes disease in healthy adults, explaining the ease with which the disease is transmitted from person to person.[26] The bacteria multiply and spread within the submucosa of the small bowel, but they rarely extend beyond the mucosa. Penetration of the mucosa is conferred genetically by large "invasion plasmids" and results in distortion of the crypts, death to intestinal epithelium, causing focal ulceration, sloughing of mucosal cells, bloody mucoid exudate into the gut lumen, and submucosal accumulation of inflammatory cells with microabscess formation.[27] Microabscesses eventually may coalesce, forming larger abscesses. Infection frequently involves the entire colon. In addition to the virulence characteristics of invasiveness, *S. dysenteriae* type 1 and, to a lesser degree, *S. flexneri* and *S. sonnei,* produce a cytotoxin, or shiga toxin, the pathogenic role of which is unclear, although it is thought to damage endothelial cells of the lamina propria, resulting in microangiopathic changes that can progress to HUS.[21]

Clinical Presentation Initial signs and symptoms include abdominal pain, cramping, and fever followed by frequent watery stools.[26] Within a few days, patients experience a decrease in fever, severe abdominal pain, and tenderness prior to the development of bloody diarrhea and other signs of dysentery (see Table 122–4). Stools are often greenish in color and contain leukocytes. Fluid and electrolyte losses may be significant, particularly in infants and elderly patients. In the early stages of the disease, stool cultures are positive. A rapid diagnostic test kit that uses DNA amplification by polymerase chain reaction is also available.

If left untreated, bacillary dysentery usually lasts about 1 week (range: 1 to 30 days). Complications are unusual but may include severe dehydration, generalized seizures, septicemia, toxic megacolon, perforated colon, arthritis, protein-losing enteropathy, and HUS. Mortality is rare, but it may be more likely with *S. dysenteriae* type I. Less than 3% of persons who are infected with *S. flexneri* will later develop Reiter syndrome, characterized by pains in the joints, irritation of the eyes, and painful urination. This can lead to chronic arthritis.[28]

TREATMENT

Shigellosis is usually a self-limiting disease. Most patients recover in 4 to 7 days, although 10% may experience a recurrence. ORT is the foundation of treatment (dysentery is not generally associated with significant fluid loss). However, intravenous fluid replacement therapy may be necessary, especially in children and the elderly.

Owing to the self-limiting nature of the illness and rapid development of antimicrobial resistance, antibiotic treatment is reserved for the elderly, those who are immunocompromised, children in daycare centers, malnourished children, and healthcare workers. Antibiotics shorten the period of fecal shedding and attenuate the clinical illness. Due to multidrug resistance, the preferred agents of choice are fluoroquinolones (ciprofloxacin, levofloxacin, or norfloxacin). A single dose is reasonable for mild to moderate illness, but for complicated bacillary dysentery or proven *S. dysenteriae* type 1 infection 5 days of therapy is recommended.[26] In children and pregnant women, azithromycin can be used.[29] Antimotility agents such as loperamide are contraindicated because they can worsen bacillary dysentery and could be involved in the development of toxic dilatation of the colon.

Salmonellosis

Epidemiology *Salmonella enterica* are gram-negative bacilli belonging to the family Enterobacteriaceae. The most prevalent *Salmonella enterica* serotypes are Typhi or Paratyphi, which cause enteric fever. Gastroenteritis (enterocolitis) is caused by *S. enterica* serotypes Typhimurium or Enteritidis. Other clinical manifestations produced by nontyphoidal salmonellosis include bacteremia, and extraintestinal localized infection.

In the United States, the largest burden of *Salmonella* infection is due to nontyphoidal serotypes, causing approximately 1.4 million cases of salmonellosis, 16,000 hospitalizations, and 600 deaths, occurring annually.[30] The incidence of salmonellosis in the United States is decreasing, which is believed to be a result of improved food-handling practices and water treatment. Salmonellosis is a disease primarily of infants, children, and adolescents. Children younger than age 5 years account for approximately 25% of all diagnosed cases. Conditions that may predispose to infection include those which decrease gastric acidity, antibiotic use, malnutrition, and immunodeficiency states. Contaminated food or water has been implicated in the majority of cases. Direct fecal–oral transmission occurs less frequently but is particularly important in children. Foods most often implicated in human salmonellosis are poultry, poultry products, beef, pork, and dairy products.[31] Pets, particularly reptiles, are a common source of infection.

Pathogenesis The incubation period, symptoms, and disease severity depend on the amount of organism ingested. The inoculum necessary for clinical illness is estimated to be 10^6 organisms,

and this infectious dose is lowered in patients with achlorhydria (gastric pH >4.0). Once ingested and successfully beyond host defense mechanisms such as low gastric pH and bile salts, organisms can attach and invade the distal ileum and proximal colon. Gastroenteritis often is characterized by massive neutrophil infiltration followed by lymphocytes and macrophages.[31] The serotypes that are responsible for human illness cause intestinal epithelial cells to secrete interleukin 8, a potent neutrophil chemo-tactic factor. Degranulation and release of toxic substances by neutrophils may contribute to inflammation and result in tissue damage, fluid secretion, or leakage across the intestinal mucosa.

Clinical Presentation Most patients experience symptoms within 72 hours of ingestion of contaminated food or water.[31] Patients often complain of nausea and vomiting followed by abdominal cramps, headache, fever, and diarrhea, although the actual presentation is quite variable. Some patients do not have increased stool frequency, whereas others have more than 1 stool per hour. Stools generally are loose and may be mucoid or bloody (dysentery-like) or both. Febrile episodes usually range between 37.7°C and 38.8°C (100°F and 102°F) but may be higher. Some evidence suggests that fever of 40°C (104°F) or higher is associated with shorter bacterial excretion. Diarrhea and fever usually resolve spontaneously within 1 to 5 days but may last 2 weeks.[31]

Stool cultures inevitably yield the causative organism if obtained early (i.e., in patients hospitalized less than 3 days). Recovery of organisms continues to decrease with time such that by 3 to 4 weeks, only 5% to 15% of adult patients are passing *Salmonella.* Infants and children tend to pass bacteria for longer periods than adults (up to 7 weeks). Chronic fecal shedding of *Salmonella* has been associated with chronic biliary infection and cholelithiasis.

Bacteremia is the most common complication of gastroenteritis. This clinical syndrome is most frequent with serovars Choleraesuis and Dublin. In addition, high-risk patients include infants, elderly, and patients with severe underlying illness or immunosuppression, including those with AIDS. The clinical syndrome is characterized by persistent bacteremia and prolonged intermittent fever with chills. Stool cultures frequently are negative. Leukocyte counts are often within the normal range. Vascular complications such as seeding of athrerosclerotic plaques or aneurysms in arterial vessels occur in 10% to 25% of adults with bacteremia.

Localized infections develop in 5% to 10% of patients with bacteremia. Extraluminal infection or abscess formation or both can occur at any site. They may follow any of the other syndromes, or they may be the primary presentation. Metastatic infections may involve bone, cysts, heart, kidney, liver, lungs, pericardium, spleen, and tumors. The clinical presentation usually is determined by the organ systems involved. Polymorphonuclear leukocyte counts often are elevated.

TREATMENT

Gastroenteritis is usually self-limiting, and fluid and electrolyte replacement is the primary mode of treatment. Most patients respond well to ORT.[31] Antimotility drugs should be avoided because they increase the risk of mucosal invasion and complications. Antibiotic therapy is not indicated in otherwise healthy adults. Antibiotics have no effect on the duration of fever or diarrhea, and their frequent use increases the likelihood of resistance and the duration of fecal shedding.[32] Antibiotics should be used in high-risk patients: (a) neonates or infants younger than age 1 year, because young children have an increased risk of complicated infection; (b) persons older than age 50 years; (c) patients with primary or secondary immunodeficiency such as AIDS, or chemotherapy patients; and (d) patients with vascular abnormalities (valvular heart disease, severe atherosclerosis), or those with prosthetic joints. Susceptibility testing is recommended because many drug-resistant strains of *Salmonella* have emerged.[10] For high-risk patients, ciprofloxacin for 5–7 days is recommended.[32] Depending on susceptibility results, azithromycin, trimethoprim-sulfamethoxazole, and amoxicillin can also be used.[32] In chronic carrier states, the choice of antibiotic should be based upon sensitivity testing of the colonizing isolate. The chronic carriage state has been reduced with long-term use of ciprofloxacin, trimethoprim-sulfamethoxazole, or amoxicillin.

Increased resistance concerns dictate that empiric therapy for life-threatening bacteremia or focal infections following nontyphoidal *Salmonella* infection should include a combination of a third-generation cephalosporin (such as ceftriaxone 2 g IV daily) and a fluoroquinolone (ciprofloxacin 500 mg orally twice daily) until the susceptibilities are known.[33] The duration of antibiotic therapy is dictated by the site of infection. Bacteremia without endovascular infection should be treated for 7 to 14 days. In documented or suspected endovascular infection, 6 weeks of intravenous therapy with ampicillin or ceftriaxone is recommended. Chloramphenicol is no longer recommended in patients with endovascular infection because of high failure rates.

Campylobacteriosis

Epidemiology The *Campylobacter* species are flagellated, curved, gram-negative rods that are thought to be one of the most common bacterial causes of diarrheal illnesses worldwide. Although there are 14 different species, *C. jejuni* is the species responsible for more than 99% of *Campylobacter*-associated gastroenteritis. In the United States, the incidence of *Campylobacter* infection decreased 26% from 1996 to 1999.[34] However, surveillance studies indicate that *Campylobacter* species remain the most commonly isolated enteric pathogen, detected two to seven times more frequently than *Salmonella* or *Shigella.* The CDC estimates that 2.4 million persons are affected each year in the United States, involving almost 1% of the entire population.

In developed countries, the peak incidence of *Campylobacter* infections occurs in children younger than age1 year and in young adults ages 15 to 44 years. The incidence is also higher in males than in females, although the reason for this is unknown. Patients with AIDS are particularly susceptible; the incidence in AIDS patients is 40 times that of the general population.[34] Most reported cases occur during the summer months, beginning in May and peaking in August. In tropical developing countries, *Campylobacter* infections are common among children younger than age 2 years, and asymptomatic infections of children and adults are more common than those seen in industrialized nations. This decrease in the case-to-infection ratio suggests that previous exposure confers immunity to the infecting strain.

The transmission of infection occurs primarily by ingestion of contaminated food or water. Although *Campylobacter* species have varied reservoirs, such as livestock, dogs, cats, and birds, the consumption of chicken is the major vector of infections in industrialized nations. Poultry products are nearly always contaminated with *Campylobacter* species during the slaughtering process, and it is estimated that 1 drop of chicken juice may contain 500 infectious organisms.[35] Although public education emphasizes safe handling and cooking of chicken, it is easy to see how simple errors may result in human illness.

Pathogenesis *Campylobacter* species are labile in acidic environments, much like *Salmonella.* Therefore, an inoculum of approximately 800 organisms is required to initiate infection. Conditions in the upper small intestine are favorable for multiplication.

Flagella-mediated adherence and tissue invasion by bacteria have been demonstrated in the jejunum, ileum, and colon. Infection results in an acute inflammatory enteritis. *C. jejuni* can produce an enterotoxin or cytotoxin.[36] Both cytotoxins and enterotoxins may be produced in many strains. Symptom manifestation depends on immunity. Patients infected with *Campylobacter* develop specific immunoglobulin (Ig) G, IgM, and IgA antibodies in serum and IgA antibodies in intestinal secretions. Volunteer studies indicate that immunity does protect against illness.

Clinical Presentation The average incubation period of *Campylobacter* is 2 to 4 days.[34] The most common presenting symptoms include diarrhea, abdominal pain, and fever. Nausea, vomiting, headache, myalgia, and malaise also may occur. Bowel movements may be numerous, bloody (dysentery-like), and foul smelling, and range from loose to watery. Cramping and abdominal pain usually are relieved by defecation. In 75% of cases, leukocytes and red blood cells are detected in the stool samples. Peripheral leukocytosis also may be present. The disease usually is self-limited to about 1 week, but it may persist for several weeks in 10% to 20% of patients. The case-fatality rate is 0.05 per 1,000 infections.

Complications, including pseudoappendicitis, pancreatitis, gastrointestinal hemorrhage, thrombophlebitis, abscess, septicemia, peritonitis, empyema, urinary tract infection, and cholecystitis, are uncommon, but occur more frequently in those who are immunocompromised. *C. jejuni* has been associated with Guillain-Barré syndrome (GBS), but the relationship is not well understood.[34] *C. jejuni* infections are a common trigger of GBS, accounting for approximately 30% of GBS cases, but the risk of developing GBS after *C. jejuni* infection appears to be low (<1 case of GBS per 1,000 *C. jejuni* infections). A reactive arthritis may develop several weeks after infection in persons with the HLA-B27 histocompatibility antigens.[28] Diagnosis is made by stool culture, but the bacteria sometimes are identifiable with Gram's stain or carbol-fuchsin stain.

TREATMENT

The primary treatment of campylobacteriosis is oral fluid and electrolyte replacement.[34] Most people recover from this self-limiting disease in 4 to 7 days. Antibiotics are not useful unless started within 4 days of the start of the illness because they do not shorten the duration or severity of diarrhea but only shorten the duration of bacterial excretion. However, antibiotics are warranted in patients with high fevers, severe bloody diarrhea, prolonged illnesses (>1 week), pregnancy, and immunocompromised states, including HIV infection (see Table 122–4).

C. jejuni is susceptible to a wide variety of antimicrobial agents. Fluoroquinolone resistance has increased, and is now 10% to 13% in the United States (41% to 88% in Europe and Asia). Resistance may be the result of the use of fluoroquinolone antibiotics in poultry feed, and the frequent use of these agents internationally in treating enteric infections. Erythromycin is considered the drug of choice due to its low cost, high efficacy, safety profile, and ease of administration. Macrolides such as clarithromycin and azithromycin are equally effective. Tetracycline, chloramphenicol, clindamycin, and aminoglycosides may be effective. Antimotility agents such as loperamide are contraindicated because slowing fecal transit time may extend the duration of infection and increase toxin mucosal invasion.

Yersiniosis

Yersinia species are non-lactose-fermenting gram-negative coccobacilli that are widely distributed in nature. The genus *Yersinia* includes six species known to cause disease in humans. *Y. enterocolitica* and, to a lesser extent, *Yersinia pseudotuberculosis,* are most likely associated with intestinal infection, but overall both are a relatively infrequent cause of diarrhea and abdominal pain. More than 50 serotypes of *Y. enterocolitica* exist; of these, serotypes 0:3, 0:8, and 0:9 are associated most frequently with enterocolitis.[37] Infections are reported commonly from northern Europe, and the peak incidence occurs during the winter months.

Children are the most likely to experience illness with *Y. enterocolitica* infection.[38] Transmission of infection occurs frequently by ingestion of contaminated food or water. The organisms have been isolated from a variety of food sources, including pigs, raw goat milk, and cow milk. Refrigeration does not deter the development of adherence and invasive virulence factors.

Y. enterocolitica invade the intestinal epithelium and penetrate the intestinal mucosa.[39] An inoculum of 10^9 organisms may be required for infection. Most strains produce an enterotoxin, but the role of toxin production in causing diarrhea is not well established. However, this infection causes mucosal ulcerations in the terminal ileum, necrotic lesions in Peyer patches, and enlargement of mesenteric lymph nodes.

Clinical Presentation These bacteria cause a wide spectrum of clinical syndromes.[38] Most patients with *Y. enterocolitica* infection present with enterocolitis that is mild and self-limiting. Symptoms include vomiting, abdominal pain, diarrhea, and fever; up to 60% of patients will have blood-streaked stools. Diarrhea resolves after 1 to 3 weeks, but bacteria excretion may continue for up to 3 months after diarrhea subsides. Most patients with this type of infection are younger than age 5 years. In older children and adolescents, mesenteric adenitis and/or terminal ileitis with fever, right lower quadrant pain, and leukocytosis are common. Mesenteric adenitis, which is difficult to distinguish from acute appendicitis, is also seen in patients infected with *Y. pseudotuberculosis*.

Approximately 10% to 30% of adult patients develop a reactive arthritis 1 to 2 weeks after recovery from enteritis. This arthritis, involving the knees, ankles, toes, fingers, and wrists, usually resolves in 1 to 4 months but may persist in approximately 10% of patients.[28] This complication is more common in persons with the HLA-B27 antigen. Other postinfection complications include erythema nodosum, exudative pharyngitis, pneumonia, empyema, and lung abscess. Although rare, *Y. enterocolitica* bacteremia has been reported in patients with diabetes mellitus, severe anemia, hemochromatosis, cirrhosis, and malignancy. Other groups at risk include the elderly and those who received frequent red blood cell transfusions (iron overload).[40] These patients are at increased risk for hepatic or splenic abscesses, peritonitis, septic arthritis, osteomyelitis, wound infections, meningitis, and endocarditis.

TREATMENT

Oral fluid and electrolyte replacement is an important initial approach. Owing to the self-limiting nature of the illness, antibiotics may not alter the time to resolution of the diarrhea or the rate of bacteriologic cure. Antibiotics should be used in high risk patients who develop bacteremia (i.e., infants younger than age 3 months and patients with cirrhosis or iron overload) or in patients with bone and joint infections.[38] The drugs of choice remains unclear. Fluoroquinolones alone or in combination with third-generation cephalosporins or aminoglycosides may be effective for *Yersinia* bacteremia or for those with bone and joint infections.[38] Other antibiotics effective in vitro are chloramphenicol, tetracyclines, and trimethoprim-sulfamethoxazole. Agents

frequently resistant to *Yersinia* are penicillin G, ampicillin, and first-generation cephalosporins.

CLOSTRIDIUM DIFFICILE

Epidemiology

C. difficile is the most commonly known cause of infectious diarrhea in hospitalized patients in North America and Europe. *C. difficile* infection (CDI) is associated with use of broad-spectrum antimicrobials, including clindamycin, ampicillin, cephalosporins, and fluoroquinolones. Other agents that have been implicated, albeit at a lower incidence rate, include aminoglycosides, erythromycin, trimethoprim-sulfamethoxazole, vancomycin, and metronidazole. Although in most cases CDI occurs during or shortly after the completion of antimicrobial therapy, disease onset can be delayed for 2 or 3 months.[41] CDI occurs most often in high-risk groups, such as the elderly, debilitated patients, cancer patients, surgical patients, patients receiving antibiotics, patients with nasogastric tubes, and patients who frequently use laxatives.

Unfortunately, the incidence and severity of disease have increased dramatically since 2000. These changes are assumed to be due to the emergence of a single-strain type (North American pulsed-field type [NAP-1]) in outbreaks.[42] NAP-1 strain is highly resistant to fluororquinolones and carries deletion mutations in a regulatory gene (tcdC) believed to inhibit toxin production, causing higher levels of toxin production responsible for more serious diseases. The NAP-1 strain is also refractory to standard therapy.

Pathogenesis

C. difficile is a gram-positive spore-forming anaerobic bacillus and causes a toxin-mediated disease. Once antibiotics disrupt normal colonic flora and colonization of *C. difficile* occurs, two toxins (A and B) are released to mediate diarrhea and colitis. This toxin production is essential in disease manifestation. Toxin A is the major pathogenic factor and has been characterized as an enterotoxin that causes intestinal fluid secretion, mucosal injury, and inflammation through actin disaggregation, intracellular calcium release, and damage to neurons. Toxin B is a nonenterotoxic cytotoxin that causes depolymerization of filamentous actin and mediates more potent damage to human colonic mucosa than toxin A. Initially, raised white and yellowish plaques form, and the surrounding mucosa may be inflamed. With progression of disease, these pseudomembranous plaques become enlarged and scatted over the colorectal mucosa.[41]

Clinical Presentation

Clinical diagnosis is based on the onset of diarrhea during or after antimicrobial use and often is associated with abdominal discomfort, fever, and polymorphonuclear leukocytosis. A spectrum of disease ranges from mild diarrhea to life-threatening toxic megacolon and pseudomembranous entercolitis.[41] In colitis without pseudomembrane formation, patients present with malaise, abdominal pain, nausea, anorexia, watery diarrhea, low-grade fever, and leukocytosis. Fulminant disease is characterized by severe abdominal pain, perfuse diarrhea, high fever, marked leukocytosis, and classic pseudomembrane formation evident with sigmoidoscopic examination.

CDI should be suspected in patients experiencing diarrhea with a recent history of antibiotic use (within the previous 3 months) or in those whose diarrhea began 72 hours after hospitalization. Diagnosis can be established by detection of toxin A or B, stool culture for *C. difficile,* or endoscopy. If the stool sample is negative, a second analysis is recommended because the testing sensitivity may be increased with repeat testing. Endoscopy should be reserved for situations where rapid diagnosis is needed, ileus is present, stool is not available, or other colonic diseases are in the differential diagnosis.

TREATMENT

Initial therapy should include discontinuation of the offending agent.[41] Fluid and electrolyte replacement therapy is necessary. Although diarrhea will resolve in up to 25% of patients within 48 hours of discontinuing the offending agent without therapy, most patients require antibiotics. Both vancomycin and metronidazole are similar in time to resolution of diarrhea, incidence of side effects, and relapse rates. Metronidazole is the drug of choice for mild to moderate CDI because its oral formation is less expensive and there are concerns for vancomycin resistant-enterococci with oral vancomycin use. In patients with severe disease, contraindication or intolerance to metronidazole, and inadequate response to metronidazole, oral vancomycin is recommended. Vancomycin must be administered orally because intravenous vancomycin does not achieve gut lumen concentrations high enough for effective bacterial elimination. In patients with an ileus (where oral vancomycin reaching site of infection is questioned) vancomycin may be delivered by retention enema or add intravenous metronidazole.

Relapse after metronidazole or vancomycin therapy occurs in approximately 20% of patients and increases in frequency with subsequent recurrences. Patients with 1 prior episode of relapse have a greater than 40% risk of additional recurrences, whereas those with 2 or more previous episodes have a greater than 60% risk.[43] Relapse typically develops in 1 to 2 weeks after stopping metronidazole or vancomycin but can be delayed for up to 12 weeks. Risk factors for recurrent CDI include a history of recurrence, advancing age, use of additional antimicrobials, and an inadequate protective immune response to *C. difficile* toxins. Management of the first relapse is identical to a primary episode because relapse is rarely due to resistance to metronidaole or to vancomycin. Instead, relapse occurs because treatment fails to eradicate the spore forms of pathogen or treatment makes patients vulnerable to another infection by impairing normal flora.

The optimal management of patients with multiple relapses is not clear. The most effective regimen is a prolonged tapered pulse-dosing of oral vancomycin and should be considered for second relapse.[43,44] Alternative regimens that have shown efficacy include drugs in rifamycin class: vancomycin + rifampin[45] or vancomycin followed by rifaximin.[46] Concern with these regimens includes drug interactions with rifampin and development of resistance, especially if either rifampin or rifaximin is used as monotherapy. Nitazoxanide is another alternative agent in patients with relapse following metronidazole therapy.[47] There are two other modalities that have been shown to have efficacy against CDI: IVIG and fecal transplantation. Individuals with low concentration of circulating IgG antitoxin are susceptible to more severe disease and frequent relapses. In those with multiple relapses due to impaired antigenic response to toxins, IVIG 400 mg/kg may be a worthwhile intervention.[48] It is, however, expensive and its efficacy is reported in case series and anecdotal reports. Fecal transplantation uses a small amount of fresh feces from a healthy donor, suspended in saline, filtered and administered through a nasogastric tube or by retention enema.[49] Although it was efficacious in a case series, it is a difficult option to offer to patients.

Agents that have lost favor due to poor efficacy or resistance include bacitracin, cholestyramine, colestipol, and fusidic acid. Probiotics using *Saccharomycin boulardii* or *Lactobacilli* species to augment colonization resistance and prevent recurrent CDI have been studied but data are too limited for recommendation.[50] Their use in conjunction with antibiotics for the treatment of relapses and their risk of bacteremia and fungemia, especially in immunocompromised hosts, require further study. Agents that are in clinical trials include Ramoplanin (a new lipoglycodepsipeptide), difimicin (an 18-membered macrocyclic antibiotic) and tolevamer (a large anionic polymer that binds *C. difficile* toxins A and B). Tolevamer is inferior to metronidazole and vancomycin in the treatment of the first episode of CDI but the relapse rate was lower.[51] An active vaccine has been studied in 1 small case series.

Drugs that inhibit peristalsis, such as diphenoxylate, are contraindicated in CDI.[41] Slowing of fecal transit time is thought to result in extended toxin-associated damage. Strict hand washing and contact precautions are imperative measures in preventing the spread of the organism. *C. difficile* can be cultured in rooms of infected individuals up to 40 days after discharge.

CLINICAL CONTROVERSY

Some investigators have found prophylaxis with competing, nonpathogenic organisms such as *Lactobacillus* spp. or *Saccharomyces* spp. to be helpful in preventing relapses in small numbers of patients with *C. difficile* infection. It is thought that these organisms help to restore the natural flora in the gut and make patients more resistant to colonization by *C. difficile* when used in conjunction with appropriate antibiotics.

ACUTE VIRAL GASTROENTERITIS

Acute viral gastroenteritis was unknown until the 1970s. Viruses are now recognized as the leading cause of diarrhea in the world, although in many cases an exact pathogen cannot be determined. In Asia, Africa, and Latin America, viral gastroenteritis accounts for an estimated 3 to 5 billion cases and is associated with 5 to 10 million deaths.[52] Viruses that cause gastroenteritis include rotavirus, norovirus (belonging to calicivirus), enteric adenovirus, and astrovirus. Other viruses, such as toroviruses, coronaviruses, picobirnaviruses, and pestiviruses, are being identified increasingly as causative agents of diarrhea. Characteristics of common viral pathogens causing gastroenteritis are outlined in Table 122–5.

ROTAVIRUSES

Epidemiology

Rotavirus is the most common cause of diarrhea in infants and children worldwide, and 1 million people die annually from the infection. In the United States, approximately 3.5 million cases of diarrhea, 500,000 physician visits, 50,000 hospitalizations, and 20 deaths occur each year in children younger than age 5 years.[52] Serologic surveys show that nearly all children are infected by age 5 years, but dehydrating diarrhea occurs primarily among young children ages 3 to 35 months during their initial infection.[53] Thereafter, young children are shielded from the severity of subsequent infection. In fact, after the initial infection with rotavirus, 40% of children are protected against subsequent infection, 75% are protected against subsequent gastroenteritis, and up to 88% are protected against severe gastroenteritis. Unfortunately, both immunocompromised children and adults are at increased risk for severe, prolonged, and even fatal rotavirus gastroenteritis.

Pathogenesis

Rotaviruses are double-stranded, wheel-shaped, RNA viruses. The outermost layer contains two structural viral proteins. The protease-cleaved protein (P protein) VP4 and the glycoprotein (G protein) VP7 define the serotype of the virus and are the basis for vaccine development. Once ingested, these strains cause diarrhea by inducing changes in transepithelial fluid balance, malabsorption as a consequence of destruction of epithelial lining of intestine, and vascular damage and ischemia of villi. Changes to the villi include shortening of villus height, crypt hyperplasia, and mononuclear cell infiltration of the lamina propria.[53]

Clinical Presentation

The incubation period of rotavirus infection is typically 1 to 3 days. Clinical manifestations vary from asymptomatic (which is common in adults) to severe nausea, vomiting, and diarrhea with dehydration. Because the first infection tends to be the most severe, dehydration and electrolyte disturbances occur more frequently in children. The symptoms begin abruptly, with vomiting often preceding the onset of diarrhea. Fever is present in a third of patients. Other signs and symptoms include respiratory symptoms, irritability, lethargy, pharyngeal erythema, rhinitis, red tympanic membranes, and palpable cervical lymph nodes. These gastrointestinal symptoms resolve in 3 to 7 days.[53]

Laboratory findings reflect the degree of vomiting, diarrhea, or both. Transient rises in liver enzymes may be seen in 60% of children hospitalized for rotavirus diarrhea. The white blood cell count is usually normal. Stools rarely contain blood or leukocytes. Rotavirus detection in stool samples is possible with an enzyme

TABLE 122-5 Characteristics of Agents Responsible for Acute Viral Gastroenteritis and Diarrhea

Virus	Peak Age of Onset	Time of Year	Duration	Mode of Transmission	Symptoms
Rotavirus	6 months–2 years	October to April	3–8 days	Fecal–oral, water, food	Vomiting, diarrhea, fever, abdominal pain, lactose intolerance
Norovirus	3 months–6 years	Peak in winter	4 days	Fecal–oral, water, shellfish	Vomiting, diarrhea
Astrovirus	<7 years	Winter	1–4 days	Fecal–oral, water, shellfish	Diarrhea, headache, malaise, nausea,
Enteric adenovirus	<2 years	Year-round	7–9 days	Fecal–oral	Diarrhea, respiratory symptoms, vomiting, fever
Pestivirus	<2 years	NR	3 days	NR	Mild
Coronavirus-like particles	<2 years	Fall and early winter	7 days	NR	Respiratory disease
Enterovirus	NR	NR	NR	NR	Mild diarrhea, secondary organ damage
Norwalk	>5 y	Variable	12–24 hours	Fecal–oral, food, aerosol	Nausea, vomiting, diarrhea, abdominal cramps, headache, fever, chills, myalgia

NR, not reported.

immunoassay and a latex agglutination assay, both of which are available commercially.

TREATMENT

Oral fluid and electrolyte replacement is the cornerstone of treatment.[53] Probiotic therapy with *Lactobacillus* may reduce the duration of diarrhea and of viral excretion. There is no role for antibiotics in acute infection. Bismuth subsalicylate, although shown to decrease the duration of diarrhea and stool output, is not recommended for routine use because of the self-limiting nature of the disease and the risk of bismuth subsalicylate overdose. Antimotility agents are not recommended because they do not decrease the duration or volume of diarrhea.

The first vaccine (RotaShield) to prevent rotavirus infection was licensed for use in the United States in 1998, but it was withdrawn after 1 year because of an increased rate of idiopathic intussusception. Post-licensure surveillance found that the risk for intussusception was the highest within 3 to 14 days after receipt of the first dose, which was estimated to be 1 case per 10,000 vaccine recipients.[54] There was also a suggestion that the risk was age-dependent, and possibly infants younger than 3 months were in less danger than older ones.

There are currently 2 vaccines that are licensed for use in the United States.[14] RotaTeq is a live, oral vaccine that contains five human/bovine reassortant rotaviruses. Because these viral strains are derived by inserting the gene encoding capsid protein from G1, G2, G3, or G4 human rotavirus strain into a bovine rotavirus backbone, they contain segmented genome from different parents and are referred to as *reassortant rotaviruses*. Four reassortant rotaviruses express one of the outer capsid proteins, G types (G1 to G4), and the fifth expresses the attachment protein, P1A. Therefore, this vaccine provides protection against the serotypes G1, G2, G3, and G4 when administered. In clinical trials, the vaccine offered 74% efficacy against gastroenteritis of any severity and 98% efficacy against severe disease.[55] This oral vaccine decreased office visits by 86%, emergency department visits by 94%, and hospitalizations by 96%. Moreover, the vaccinated children showed similar cases of intussusception as nonvaccinated children (six cases versus five cases; adjusted relative risk of 1.6; confidence interval [CI] = 0.4 to 6.4). Other serious side effects, including deaths, were similar among vaccine and placebo recipients. There were small but significantly greater rates of vomiting, diarrhea, nasopharyngitis, otitis media, and bronchospasm among vaccine recipients. Three doses at age 2, 4, and 6 months are recommended.[14]

Another rotavirus vaccine, RotaRix, is a live-attenuated human rotavirus vaccine prepared from a single human strain of P1A G1. A trial of this vaccine has shown a clinical efficacy of 79% against gastroenteritis of any severity and 96% efficacy against severe rotavirus disease. Rotarix reduced hospitalizations by 100%, medically attended visits by 92% in the first rotavirus season, and reduced hospitalizations by 96% through 2 seasons. There were no increases in intussusception among vaccine recipients.[56] Two doses, administered at 2 and 4 months are recommended.[14]

CALICIVIRUSES

The human caliciviruses are assigned to two genera, Norovirus and Sapovirus, responsible for gastroenteritis. The Norovirus causes illness in all age groups, whereas Sapovirus causes illness mainly in children. Although the relative importance of these viruses as causes of GI infections is unknown, Noroviruses are important causes of outbreaks.[57] The Norwalk virus was the first norovirus to be described in 1972 in Norwalk, Ohio.

As with most viruses, the epidemiology of the norovirus is not well understood. The disease commonly affects children and adults, but it is not often associated with disease in neonates and preschool children.[57] Outbreaks occur throughout the year and have been documented in families, healthcare systems, cruise ships, and college dormitories.

The pathophysiology of this disease is similar to that caused by the rotavirus. Human volunteer studies show histopathologic changes in the jejunum within 24 hours of viral challenge, and clinical manifestations appear within 48 hours.[57] The exact mechanisms of virus-induced vomiting or diarrhea are unknown. Brush-border enzyme activity may be decreased, resulting in lactose intolerance, but it generally returns to preinfection levels within 2 weeks. Virus shedding in the stool can occur over the first 24 to 48 hours after illness.

Gastroenteritis caused by norovirus is characterized by sudden onset of abdominal cramps with nausea, vomiting, or both. Adults frequently experience non-bloody diarrhea; children experience vomiting more often than diarrhea. Other complaints are myalgia, headache, and malaise, which are accompanied by fever in approximately 50% of patients. Signs and symptoms generally last 12 to 48 hours.

The disease is generally self-limiting. Oral fluid and electrolyte replacement should be used, if necessary. A norovirus vaccine produced via expression of viral antigens in a baculovirus or transgenic plants is under investigation.[58]

OTHER POTENTIAL VIRAL PATHOGENS

Astroviruses increasingly are being recognized as important causes of gastroenteritis. Astroviral illness is often reported in children younger than age 3 years, but it has also been described in adults and the elderly.[59] Astroviruses have been detected in the stools of children, as well as in patients with immunodeficiency conditions such as HIV infection or bone marrow transplantation. Outbreaks have been reported in schools, daycare settings, and pediatric wards. The pathogenesis of astroviral infection is believed to be similar to that noted for rotavirus. The clinical presentation consists of diarrhea, headache, malaise, nausea, and to lesser extent, vomiting. These symptoms appear to be similar to those observed with rotavirus but milder. Maintenance of adequate hydration and electrolyte balance is the only therapeutic issue. The duration of viral shedding may be as long as 35 days.

Adenovirus is an icosahedral virus previously associated with respiratory, ocular, and genitourinary infections; however, serotypes 40 and 41 are GI pathogens. Low-grade fever and respiratory symptoms are also common. The diagnosis can be made by enzyme immunoassay that identifies serotypes.

Although less commonly associated with severe GI disease, pestivirus, torovirus, and coronavirus-like particles have been recovered from diarrheal stools. In HIV-infected patients, the presence of diarrhea is associated with virus in 35% of stool specimens.[60] Astrovirus, picobirnavirus, calicivirus, and adenovirus appear to be the most commonly isolated viral pathogens. Table 122–5 presents specific characteristics of these agents.

TRAVELER'S DIARRHEA

Traveler's diarrhea describes the clinical syndrome manifested by malaise, anorexia, and abdominal cramps followed by the sudden onset of diarrhea that incapacitates many travelers. Traveler's diarrhea interferes with planned activities or work in 30% of those

affected.[61] In particular, an increased risk lies with North Americans and northern Europeans traveling to Latin America, southern Europe, Africa, and Asia. The highest risk is observed with patients with immuno-compromised conditions, achlorhydria, inflammatory bowel disease, and people with chronic debilitating medical conditions. Overall, an estimated 20% to 50% of people traveling to high-risk areas will develop the illness.

5 The onset of symptoms usually occurs during the first week of travel but can occur anytime during the visit or after returning home. Traveler's diarrhea is caused by contaminated food or water. The most common pathogens are bacterial in nature and include ETEC (20% to 72%), *Shigella* (3% to 25%), *Campylobacter* (3% to 17%), and *Salmonella* (3% to 7%).[61] Viruses (0% to 30%) are also potential causes, as are parasites, although they are rare during short-term travels, accounting for less than 5% of cases. The severity of the syndrome is determined by the number of stools per day and the presence or absence of cramping, nausea, and vomiting. Mild diarrhea is defined as 1 to 3 loose stools per day that are associated with abdominal cramps lasting less than 14 days. Moderate diarrhea indicates more than 4 loose stools daily associated with dehydration, and severe diarrhea is defined as presence of fever or blood in stools. Traveler's diarrhea is rarely life-threatening and in most cases, symptoms resolve in several days without treatment. Travelers to high-risk areas should pack a kit that includes a thermometer, loperamide, 3 days of antibiotics (see Prevention below), oral rehydration solution salts, and a water purification method.[61]

PREVENTION

6 Patient education in avoiding high-risk food and beverages should be the best method for minimizing the risk. High-risk foods and beverages include raw or undercooked meat and seafood, moist foods served at room temperature, fruits that cannot be peeled, vegetables, milk from a questionable source, hot sauces on the table, tap water, unsealed bottled water, iced drinks, and food from a street vendor. Slogans such as "Peel it, boil it, cook it, or forget it" remind travelers to avoid contaminated food and to use water purification or reliable bottled beverages. Unfortunately, a recent meta-analysis concluded that the incidence of diarrhea was similar in travelers who followed the old adage and those that engaged in riskier eating habits.[62] A potential reason for a lack of difference may be due to the fact that cooking foods does not always kill pathogens and food should not be considered safe unless it is cooked until steaming hot. Nonetheless, advisement of avoidance measures regarding safe foods, beverages, and eating establishments is recommended to heighten awareness.

Bismuth subsalicylate 524 mg (2 tablets, tablespoonfuls) orally four times daily for up to 3 weeks is a commonly recommended prophylactic regimen.[63] Bismuth subsalicylate may inhibit enterotoxin activity and prevent diarrhea. Persons taking this regimen should be informed of adverse events, including temporary black discoloration of tongue and stools, and, rarely, tinnitus.

Although efficacy of prophylactic antibiotics have been documented, their uses are not recommended for most travelers owing to potential side effects of antibiotics (e.g., photosensitivity), predisposition to other infections such as CDI or vaginal candidiasis, the increased risk of selection of drug-resistant organisms, cost, lack of data on the safety and efficacy of antibiotics given for more than 2 or 3 weeks, and availability of rapidly effective antibiotics for treatment. Prophylactic antibiotics (see Table 122–4) are recommended only in high-risk individuals or in situations in which short-term illness could ruin the purpose of the trip, such as a military mission.[64] A fluoroquinolone is a drug of choice when traveling to most areas of the world.[61,64] Due to fluoroquinolone-resistance among *Campylobacter* spp., azithromycin can be considered when traveling to South Asia and Southeast Asia.

A nonabsorbed oral rifamycin, rifaximin, has activity against enteric pathogens and may have a role in prevention of traveler's diarrhea in select populations. A randomized, double-blind trial of rifaximin 200 mg once, twice, or three times daily with meals for 2 weeks resulted in equal protection of 72% with each of the three dosing regimens compared to placebo.[65] Since rifaximin is effective against traveler's diarrhea due to noninvasive strains of *E. coli*, this agent should be reserved for travel regions where *E. coli* predominates, such as Latin America and Africa. Rifaximin has a tolerability and safety profile comparable to that of placebo. The concern with this class of agents is emergence of resistance when used as monotherapy.

TREATMENT

Traveler's Diarrhea

The goals of treatment are to avoid dehydration, reduce the severity and duration of symptoms, and prevent interruption to planned activities. Fluid and electrolyte replacement should be initiated at the onset of diarrhea. ORT is generally not required in otherwise healthy individuals; flavored mineral water ad libitum offers a good source of sodium and glucose.[64] In infants and young children, elderly, and those with chronic debilitating medical conditions, ORT is recommended. For symptom relief, loperamide (preferred because of its quicker onset and longer duration of relief relative to bismuth) may be taken (4 mg orally initially and then 2 mg with each subsequent loose stool to a maximum of 16 mg/day in patients without bloody diarrhea and discontinued if symptoms persist for more than 48 hours). Other symptomatic therapy in mild diarrhea includes bismuth subsalicylate 525 mg every 30 minutes up to 8 doses. There is insufficient evidence to warrant the recommendation of probiotics.

Since behavioral modification has limited efficacy and chemoprophylaxis is not recommended in most travelers, the current recommendation relies on self treatment. Most trials indicate that a single dose or up to three days will improve the condition within 24 to 36 hours, shortening the duration of diarrhea by 1–2 days.[66,67] A single dose of fluoroquinolone is recommended initially and if diarrhea is improved within 12–24 hours, antibiotic should be discontinued. Otherwise, it can be continued for up to three days. A fluoroquinolone is recommended when traveling to most areas of the world. When fluoroquinolone-resistant *Campylobacter* is common, such as in south Asia and Southeast Asia, azithromycin can be used.[68] Azithromycin can also be used in pregnant women and children younger than age 16 years. Empiric treatment of young children should be cautioned.

Rifaximin was as effective as a 3-day course of ciprofloxacin in shortening the duration of diarrhea in noninvasive traveler's diarrhea.[69] However, rifaximin was not as effective in patients with fever and bloody diarrhea and in those with invasive pathogens. Therefore, a 3-day course of rifaximin has been approved for the treatment of traveler's diarrhea caused by noninvasive strains of *E. coli* in people ≥ 12 years of age and can be considered when traveling to areas where E. coli-associated traveler's diarrhea is common, such as Mexico and Jamaica.

For rapid improvement in symptoms, antibiotic therapy with adjustive treatment with loperamide has shown benefit.[70] All clinical trials concluded that the combination therapy was safe and worsening of disease with the use of antimotility treatment has not been encountered.

CLINICAL CONTROVERSY

Most trials have shown that a short course of antibiotic therapy reduces the duration of traveler's diarrhea by 1–2 days with mild side effects. Some clinicians advocate a self-treatment with antibiotics for moderate to severe traveler's diarrhea, while others urge a more cautious approach. The final decision on self-treatment should rely on discussions with individual travelers, taking into consideration their ability and willingness to adhere to prevention strategies and to tolerate diarrheal illness during the trip.

FOOD POISONING

7 Food poisoning results from the ingestion of food containing pathogenic microorganisms, preformed toxins that were produced by microorganisms, or other toxic compounds. In the United States, food-borne disease causes approximately 76 million illnesses, 325,000 hospitalizations, and 5,200 deaths each year.[3] Food-borne transmission may account for up to 35% of acute gastroenteritis cases caused by unknown agents. A number of bacteria can cause food poisoning (Table 122–6). Common bacterial (*Campylobacter, Salmonella, Shigella, E. coli, Yersinia, Vibrio*) and viral (Norovirus) causes of GI infections were discussed in the preceding sections. Other common food-borne pathogens that cause gastroenteritis include *S. aureus, Bacillus cereus, C. perfringens,* and *Clostridium botulinum*. Unfortunately, sporadic illnesses caused by these agents are not reportable through passive or active systems, and thus it is difficult to determine their disease burden.

Because food-borne disease can appear as sporadic cases or outbreaks, the diagnosis should be suspected whenever two or more people present with acute gastrointestinal or neurologic manifestations after sharing a meal within the previous 72 hours. Important clues about etiologic agents can be gathered from demographic information (age, gender, etc.), the clinical syndrome, incubation period, medical history, type of foods consumed, seasonality, and geographic location of the outbreak.

Staphylococcal food poisoning results from the ingestion of food contaminated by an enterotoxin produced by certain strains of *S. aureus* growing within the food.[71] Enterotoxin production generally results from leaving foods at room temperature, allowing the staphylococci to grow. Symptoms are rapid in onset, generally occurring within 1 to 6 hours of ingestion of preformed toxin-containing foods. The condition is characterized by nausea and vomiting (75%), although abdominal cramps and diarrhea also may be present. Symptoms resolve in less than 12 hours. ORT should be provided in severe cases, but antibiotics are not indicated.

B. cereus causes two different types of clinical syndromes.[72] The first one is characterized by a short incubation period with vomiting, abdominal cramps, and to a lesser extent, diarrhea, within 1 to 6 hours of ingestion of contaminated food. This syndrome is caused by a preformed heat-stable toxin. Similar to staphylococcal food poisoning, illnesses caused by *B. cereus* usually last less than 12 hours. The second syndrome has a longer incubation period (8 to 16 hours) and is caused by toxins produced in vivo after the ingestion of contaminated food. In this syndrome, patients experience diarrhea, abdominal cramps, and less frequently, vomiting. The heat-labile enterotoxin produced in this syndrome activates intestinal adenylate cyclase and causes intestinal fluid secretion. This illness usually resolves within 24 hours, but symptom durations of several days to weeks also have been observed.

Food-borne *C. perfringens* infection may present as two distinct syndromes.[73] Type A organisms are seen in Western nations and result in a 24-hour illness characterized by watery diarrhea and epigastric pain. Symptoms generally resolve within 24 hours. This enterotoxin-related syndrome damages the brush borders of

TABLE 122-6 Food Poisonings

Organism	Time to Symptoms (Hours)	Principal Foods	Peak Incidence (U.S.)	Principal Mechanism of Pathophysiology	Duration	Treatment
Staphylococcus aureus	1–6	Salad, pastries, ham, poultry	Summer	Preformed toxins A–E (heat stable)	12 hours	Supportive
Bacillus cereus	1–6	Meats, vegetables, fried rice	None	Preformed toxin	12 hours	Supportive
	8–16			Toxin production (in vivo)	24 hours	Supportive
Clostridium perfringens (type A)	6–24	Meats, poultry	Fall, winter, spring	Toxin production (in vivo)	24 hours	Supportive
Vibrio parahaemolyticus	16–72	Shellfish	Spring, summer, fall	Toxin production and tissue invasion	2–7 days	Supportive
Salmonella spp.	16–48	Beef, poultry, water, eggs, dairy products	Summer	Tissue invasion	2–7 days	Supportive
Shigella spp.	16–48	Salad, water	Summer	Tissue invasion	2–7 days	Supportive
EPEC	16–48	Water	None	Tissue invasion	2–7 days	Supportive
Campylobacter	16–48	Poultry, dairy products, clams, water	Spring, summer	Tissue invasion	2–7 days	Supportive
ETEC	16–72	Water	None	Toxin production (in vivo)	1–7 days	Supportive
Vibrio cholerae	16–72	Water		Toxin production (in vivo)	2–12 days	Supportive, antibiotics
Yersinia enterocolitica	16–48	Dairy products		Toxin production and/or tissue invasion	1–30 days	Supportive
Clostridium botulinum	12–72	Canned fruits, vegetables, meats, honey	None	Preformed toxins A, B, and E (children and adults)		
				Toxin production (in vivo) (infants)		Supportive (including mechanically assisted ventilation), trivalent antitoxin

EPEC, enteropathogenic *E. coli*; ETEC, enterotoxigenic *E. coli*.

epithelial cells at the villus tips to cause a noninflammatory diarrhea. Type C organisms can be found in undercooked pork and occur in underdeveloped tropical regions. Type C organisms can produce a toxin-related syndrome called *enteritis necroticans,* which is a coagulative transmural necrosis of the intestinal wall. This syndrome can result in intestinal perforation leading to sepsis and mortality in approximately 40% of victims.

Food-borne botulism results from the ingestion of food contaminated with preformed toxins or toxin-producing spores from *C. botulinum. C. botulinum* poisoning is relatively rare; only 110 cases are reported per year in the United States.[74,75] Botulism is almost always associated with improper preparation or storage of food. Seven distinct toxins (A to G) have been described. The toxins, which are produced by the bacteria and released on lysis, are the most potent biologic or chemical toxins known to humans. The toxin prevents the release of acetylcholine at the peripheral cholinergic nerve terminal. Toxin activity has prompted the use of minute locally injected doses to treat select spastic disorders, such as blepharospasm, hemifacial spasm, and certain dystonias.
